About the Editors

Russell A. Barkley, PhD, ABPP, ABCN, is Clinical Professor of Psychiatry and Pediatrics at the Medical University of South Carolina in Charleston. He is the author of numerous bestselling books for both professionals and the public, and has worked with children, adolescents, and families for over 35 years. His website is *www.russellbarkley.org.*

Eric J. Mash, PhD, is Professor Emeritus of Psychology at the University of Calgary and Affiliate Professor in the Department of Psychiatry at Oregon Health and Science University. He has served as an editor, editorial board member, and editorial consultant for many scientific and professional journals, and has edited and authored numerous books and journal articles related to child and adolescent psychopathology, assessment, and treatment.

Preface

Research in child, adolescent, and developmental psychopathology continues to flourish, even more so than when the first edition of this text was published. Previously recognized disorders are even better delineated than they were only a few years ago, and a few new ones seem to have been discovered along the way. The publication rate in this field is extraordinary, with many journals now focusing exclusively on childhood mental illness and health, and numerous articles on children appearing each month in journals that were once the exclusive domains of adult psychopathology. To those of us who take a developmental view of psychopathology, this is a most gratifying state of affairs as we come to recognize the roots of many adult disorders in childhood and adolescence. The down side, of course, is that even the expert researchers in the various disorders that constitute this field find it harder than ever to keep abreast of research findings appearing at such a rapid clip. And woe to the clinical professionals who must deal with these childhood disorders: They may find themselves quickly and hopelessly behind in the advancements occurring in the understanding of these clinical conditions. Hence the need for a volume such as this, and especially for its third edition, to assist the clinical professional, student, and even expert in remaining current on child and adolescent psychopathological disorders.

Now more than ever, the field of child psychopathology epitomizes the dynamic, accumulative, and self-correcting nature of the scientific enterprise, as new findings expand upon and are assimilated with the established facts in any given disorder. Often these new findings challenge older theoretical or conceptual assumptions or more explicit models of these disorders, at times even leading to small-scale paradigm shifts in perspective. In short, the literature on child and adolescent psychopathology is alive, well, prosperous, and rapidly advancing. Old questions undoubtedly get answered, but along the way those answers raise new questions for researchers to pursue in ever more complex programs of research on each of the childhood disorders covered here. Although the pace and excitement levels vary considerably across different areas of child psychopathology, within each area the eager anticipation of new knowledge remains palpable as new lines of research and methodologies—such as neuroimaging, behavioral and molecular genetics, structural equation modeling, and longitudinal designs—come to overlap old ones and so provide greater opportunities to better understand these disorders.

The challenge remains for this third edition as it was for the first: How are we to capture the current status of this rapidly evolving field? Our answer was again to identify those experts who

have dedicated their professional careers to these disorders, and let them—unfettered by fashion or the editors' pet perspectives—tell us what they have learned. In other words, we tried to find the most knowledgeable professionals on particular disorders and asked them to provide up-to-date and comprehensive summaries of the nature of the disorders in which they have specialized. We asked only that their discussions be grounded in their respective bodies of scientific literature, eschewing clinical lore, dogmatic wisdom, the sayings of the guru *du jour*, or political agendas. We also asked that they set aside the concerns of assessment and treatment of their respective disorders, so as to have ample room for the burgeoning findings on the disorders themselves. These other topics are the focus of related books (Mash & Barkley, 2006, 2007).

In essence, each author or group of authors was once more challenged to answer these basic questions: "What do we know about this disorder?", "What are the implications for future research into further understanding the disorder?", and, just as important, "Where are the current limitations or gaps in our knowledge that deserve future attention?" If sound, scientifically grounded theoretical or conceptual models of the disorder exist, then these were also to be reviewed. In addressing these questions, the experts assembled here were directed to cover (1) the nature of the behavior, symptoms, and/or cognitive and emotional deficits that typify the core of each disorder; (2) the historical perspective; (3) any criteria that exist to establish its presence (diagnosis) and a candid appraisal of those criteria; (4) epidemiological knowledge pertaining to the prevalence, gender distribution, and ethnic and cultural factors associated with the disorder; (5) the developmental course and varied pathways shown to be associated with the disorder; (6) the psychiatric, psychological, and social disorders or difficulties that most often coexist with the disorder (comorbidity); and (7) a survey of those things believed to give rise to the disorder (etiology). Once more, we believe that the many authors assembled here have done a marvelous job accomplishing their charge. We trust the reader will concur.

As before, we are indebted to the professionals who agreed to write for this edition on their respective disorders. We genuinely appreciate the substantial time commitment they have made to writing their chapters, many of which are major updates of their previous work. Many others deserve our gratitude as well, including Kitty Moore, Sawitree Somburanakul, Marie Sprayberry, and Laura Specht Patchkofsky, for shepherding the manuscript through the production process. Special thanks are also owed to our long-time friends, the founders of The Guilford Press, Seymour Weingarten (Editor-in-Chief) and Bob Matloff (President), for more than 30 years of support for our various books, including this one. Last, but hardly least, we thank our families—Heather Mash, and Pat, Ken, and Steve Barkley—for relinquishing the family time such a project requires, and for their support, patience, and encouragement of our careers in this field.

INTRODUCTION TO CHILD PSYCHOPATHOLOGY

CHAPTER 1

Child Psychopathology

A Developmental–Systems Perspective

ELIZABETH P. HAYDEN
ERIC J. MASH

This volume provides a comprehensive account of the diagnosis, phenomenology, developmental pathways, correlates, causes, and outcomes of psychopathology in children.[1] Our understanding of developmental psychopathology has grown exponentially over the past several decades (Beauchaine & Hinshaw, 2013; Cicchetti, 2006; Cicchetti & Toth, 2009; Mash & Wolfe, 2013; Rutter, 2005). New conceptual frameworks and findings, as well as advances in knowledge and methods, continue to further our understanding of childhood disorders (Granic, 2005; Iacono & Malone, 2011; Moffitt, 2005; Roth & Sweatt, 2011; Rutter & Sroufe, 2000; Sameroff & Mackenzie, 2003), as well as our ability to assess and treat children with problems (Gunnar, Fisher, & The Early Experience, Stress, and Prevention Network, 2006; Kraemer et al., 2003; March, 2009; Mash & Barkley, 2006; Weisz, Sandler, Durlak, & Anton, 2005). However, this understanding is tempered by the often unsystematic and fragmented fashion in which research findings in child psychopathology have accrued, and by the conceptual and research complexities inherent in the study of such a rapidly changing and socially embedded organism as the child (Hinshaw, 2001; Sameroff & Mackenzie, 2003). In this introductory chapter, we address several central themes and issues related to conceptualizing childhood dysfunction and its many determinants. In doing so, we provide a developmental–systems framework for understanding child psychopathology—one that emphasizes the role of developmental processes, the importance of context, and the influence of multiple and interacting events and processes in shaping adaptive and maladaptive development.

FACTORS THAT COMPLICATE THE STUDY OF CHILD PSYCHOPATHOLOGY

Since modern views of mental illness began to emerge in the late 18th and early 19th centuries, the study of psychopathology in children has lagged behind that of adults (Silk, Nath, Siegel, & Kendall, 2000). For example, in 1812, Benjamin Rush, the first American psychiatrist, suggested that children were less likely to suffer from mental illness than adults because the immaturity of their developing brains would prevent them from retaining the mental events that caused insanity (Silk et al., 2000). However, it is now well established that many childhood disorders are common, early-occurring, and chronic, and that they exact a high toll from children, their families, and society (Costello, Egger, & Angold, 2006; Costello, Foley, & Angold, 2006). Furthermore, disorders of childhood often show significant homo- and heterotypic continuity with later

child and adult psychopathology (Bufferd, Dougherty, Carlson, Rose, & Klein, 2012; Copeland, Shanahan, Costello, & Angold, 2009; Reef, Diamantopoulou, van Meurs, Verhulst, & van der Ende, 2009), further supporting the relevance of childhood psychopathology for long-term adjustment. Looking backward from adulthood, epidemiological researchers have found that many adults with a mental disorder first developed psychopathology as children (Kessler et al., 2005). Thus interest in the study of child psychopathology has rightly increased dramatically.

However, an array of unresolved issues hampers progress in the investigation of psychopathology in children. Critically, issues concerning the conceptualization and definition of psychopathology in children continue to be vigorously debated (Rutter & Uher, 2012). Until fairly recently, much of the field's accumulated knowledge about the phenomenology of disorders of childhood was extrapolated from work with adults. For example, only in recent decades have child-focused models of depressive disorders emerged (e.g., Abela & Hankin, 2008). While it is well established that children can and do meet criteria for depression derived largely from research with adults, it is also clear that there are key differences in the presentation of the disorder across development (Rohde, Lewinsohn, Klein, Seeley, & Gau, 2013; Weiss & Garber, 2003). Furthermore, in contrast to adult forms of the disorder, evidence for the genetic basis of childhood depression is decidedly mixed (Rice, 2010), suggesting that aspects of models of adult depression may not extrapolate well to earlier manifestations of the disorder. This is but one example of the complexities regarding continuities and discontinuities of disorders across development.

Even in studies conducted with children, much of our knowledge is based on findings obtained at a single point in a child's development and in a single context. Although useful, such findings provide still photographs of moving targets and fail to capture the dynamic changes over time that characterize most forms of child psychopathology (Achenbach & Dumenci, 2001; Lewis & Granic, 2000). Although contextual models (e.g., Bronfenbrenner, 1977) and longitudinal approaches (e.g., Robins, 1966) have been applied to the field of child study for decades, researchers have only fairly recently begun to use developmentally sensitive systems-oriented models to account for the emergence of psychopathology in children (Granic, 2005; Sameroff, 2000). While longitudinal studies have become much more common, such studies are complicated by multiple issues including the question of how to best implement developmentally sensitive measures that can differentiate between true change and stability across a broad span of development from change in measurement strategy (Singer & Willett, 2003, pp. 13–14). In addition, many prior studies have not consistently attended to the broader familial, social, and cultural contexts in which atypical child development occurs (Davies & Cummings, 2006; Marks, Patton, & García Coll, 2011; Serafica & Vargas, 2006), often focusing solely on intrinsic characteristics of the child to the neglect of the broader context in which development unfolds.

The study of child psychopathology is further complicated by the fact that many childhood problems are not narrow in scope or expression, and that most forms of psychopathology in children are known to overlap and/or coexist with other disorders (Angold, Costello, & Erkanli, 1999; Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Drabick & Kendall, 2010; Lilienfeld, 2003). For example, it has been established for some time that there is pervasive overlap among such problems as child maltreatment, violence, emotional and behavioral disorders, substance abuse, delinquency, and learning difficulties, between childhood anxiety and depression and between reading disabilities and anxiety and depression (e.g., Garber & Weersing, 2010; Oshri, Rogosch, & Cicchetti, 2013; Seligman & Ollendick, 1998; Willcutt & Pennington, 2000b). Many behavioral and emotional disturbances in youth are also associated with specific physical symptoms and/or medical conditions and poor health outcomes (Costello, Egger, & Angold, 2006; Nigg, 2013; Pinquart & Shen, 2010; Reynolds & Helgeson, 2011; Spady, Schopflocher, Svenson, & Thompson, 2005).

It is also the case that distinct boundaries between many commonly occurring childhood behaviors (e.g., noncompliance, defiance) and those problems that come to be labeled as "disorders" (e.g., oppositional defiant disorder) are not easily drawn (e.g., Loeber, Burke, Lahey, Winters, & Zera, 2000). There is mounting evidence that most forms of psychopathology differ *in degree* from normative behavior, rather than *in kind* (i.e., distinctions between normal and abnormal behavior are typically quantitative, rather than qualitative; see Coghill & Sonuga-Barke, 2012, for a review of this issue in child psychopathology). Furthermore, judgments of deviancy often depend as much on other child characteristics (e.g., age, sex, intelligence), the situational appropriateness of a child's behavior, the social and cultural context in which judgments are made,

and the characteristics and decision rules of adults who make these judgments as they do on any specific behaviors displayed by the child (Achenbach, 2000; De Los Reyes & Kazdin, 2005; Mash & Barkley, 2007).

It has become increasingly evident that most forms of child psychopathology are etiologically heterogeneous and cannot be attributed to a single unitary cause. Although a handful of rare disorders (e.g., phenylketonuria, fragile-X intellectual disability, Rett's disorder) may be caused by single genes, behavioral and molecular genetics research indicate that more common and complex disorders are likely the result of multiple genes (Goldsmith, Gottesman, & Lemery, 1997; McGuffin, Riley, & Plomin, 2001; O'Conner & Plomin, 2000), and that most forms of child psychopathology are likely to have an oligo- or polygenic basis, involving susceptibility genes that interact with one another and with environmental influences to result in observed levels of impairment (Dodge & Rutter, 2011; Dodge & Sherrill, 2007; Moffitt, Caspi, & Rutter, 2006; State, Lombroso, Pauls, & Leckman, 2000). Child and family disturbances are likely to result from multiple, frequently co-occurring, reciprocal, and interacting risk factors, causal events, and processes (e.g., El-Sheikh, Keiley, Erath, & Dyer, 2013; Jaffee & Price, 2007; Rutter, 2007a). Contextual events exert considerable influence in producing child and adolescent disorders—an influence that is almost always equivalent to, or greater than, those factors usually thought of as residing "within" the child (Davies & Cummings, 2006; Reiss & Neiderhiser, 2000; Rutter, 2000). Furthermore, it has become increasingly clear that genetic influences on disorder risk can no longer be assumed to be static in their effects, as the functional impact of polymorphisms is further moderated by an array of regulatory processes known as "epigenetic effects" (Mill, 2011; Zhang & Meaney, 2010), some of which unfold in response to environment conditions. For example, animal models indicate that epigenetic effects may account for the influence of early caregiver behavior on offspring outcomes via its impact on the expression of specific genes (Weaver, Meaney, & Szyf, 2006). Life experiences that alter gene expression may also account for monozygotic twin discordance on highly heritable psychiatric phenotypes (e.g., Petronis et al., 2003). The best way to capture this dynamic interplay between genetic and environmental risks with respect to psychopathology processes has yet to be determined.

Numerous risk markers for child psychopathology have been identified, including genetic influences (e.g., Goodyer, Bacon, Ban, Croudace, & Herbert, 2009; Gotlib, Joormann, Minor, & Hallmayer, 2008; Sheikh et al., 2013); temperament (e.g., Hayden, Klein, Durbin, & Olino, 2006; Olino, Klein, Dyson, Rose, & Durbin, 2010); insecure child–parent attachments (e.g., Lee & Hankin, 2009; Priddis & Howieson, 2012); social-cognitive deficits (e.g., Luebbe, Bell, Allwood, Swenson, & Early, 2010; Zadeh, Im-Bolter, & Cohen, 2007); deficits in social learning (e.g., Arsenio & Lemerise, 2010; Lansford, Malone, Dodge, Pettit, & Bates, 2010); emotion regulation and dysregulation (e.g., Feng et al., 2009; Tortella-Feliu, Balle, & Sesé, 2010); effortful control and related constructs (Eisenberg et al., 2005; Gusdorf, Karreman, van Aken, Dekovic, & van Tuijl, 2011); neuropsychological and/or neurobiological dysfunction (e.g., Cicchetti & Cannon, 1999; Lopez-Duran, Kovacs, & George, 2009); maladaptive patterns of parenting and maltreatment (e.g., Beauchaine, Neuhaus, Zalewski, Crowell, & Potapova, 2011; Cicchetti & Toth, 2005; Harkness, Stewart, & Wynne-Edwards, 2011; Lovejoy, Graczyk, O'Hare, & Neuman, 2000); parental psychopathology (e.g., Goodman & Gotlib, 1999; Pettit, Olino, Roberts, Seeley, & Lewinsohn, 2008); parental discord (e.g., Fear et al., 2009; Pagani, Japel, Vaillancourt, Côté, & Tremblay, 2008; Shelton & Harold, 2008); limited family resources and other poverty-related life stressors (e.g., Dupéré, Leventhal, & Lacourse, 2009; Najman et al., 2010; Schreier & Chen, 2013; Tracy, Zimmerman, Galea, McCauley, & Vander Stoep, 2008); institutional deprivation (e.g., Ellis, Fisher, & Zaharie, 2004); and a host of other factors. However, these factors cannot be understood in isolation, and for most disorders, research does not support granting central etiological status to any single risk or causal factor (e.g., Sameroff, 2010).

Since the many causes and outcomes of child psychopathology are often interrelated and operate in dynamic and interactive ways over time, they are not easy to disentangle. The designation of a specific factor as a cause or an outcome of child psychopathology usually reflects (1) the point in an ongoing developmental process at which the child is observed, and (2) the perspective of the observer. For example, a language deficit may be viewed as a disorder in its own right (e.g., language disorder), the cause of other difficulties (e.g., impulsivity), or the outcome of some other condition or disorder (e.g., autism spectrum disorder). In addition, biological and environmental determinants interact at all periods of development. For example, Belsky and de Haan (2011) recently noted that the characteristic

styles parents use influence critical patterns of cortical and subcortical development across childhood and well into adolescence. Consistent with this, Dougherty, Klein, Rose, and Laptook (2011) reported that familial depression and parental hostility interacted to predict heightened cortisol reactivity to stress in a sample of community-dwelling preschoolers—a finding that suggests altered activity of the stress-regulating hypothalamic–pituitary–adrenocortical (HPA) system among children with multiple facets of risk for psychopathology. The majority of this work has focused on the impact of severe early adversity (e.g., maltreatment), so that far less is known about the impact of more normative experiences on children's brain development. Still, these and many other findings indicate that early experiences may shape neural structure and function, which may then create dispositions that direct and shape a child's later experiences and behavior (Cicchetti & Walker, 2001; Fox, Zeanah, & Nelson, 2012; Glaser, 2000; Kaufman & Charney, 2001).

In a volume covering child psychopathology, it is also worth noting that there may be issues related to the stigma of mental illness with particular relevance to children. Although definitions of stigma have varied across studies, it appears to be a multidimensional construct that is not well characterized with respect to disorders of childhood, relative to adulthood. Stigma can be experienced across different contexts and targets (Mukolo, Heflinger, & Wallston, 2010), and appears to play a role in decreasing the likelihood that services are sought for children with a mental disorder, particularly in minority groups and cultures (e.g., Yeh, McCabe, Hough, Dupuis, & Hazen, 2003). Differentiating the consequences of mental health stigma from those related to the symptoms of disorder can be difficult and has not always been closely attended to in research designs (e.g., caregiver strain could stem from both children's symptoms of disorder and parents' own symptoms, as well as perceived negative responses to the children's status as patients; Brannan & Heflinger, 2006). Additional work on the origins and role of stigma, especially as it pertains to the willingness of families to seek care or to participate in basic science on the etiology of disorder, is therefore critical.

As will be discussed throughout this volume, current models of child psychopathology seek to incorporate the roles of evolved mechanisms; neurobiological factors; early parent–child relationships; attachment processes; a long-term memory store that develops with age and experience; micro- and macrosocial influences; cultural factors; age and gender; and reactions from the social environment as variables and processes that interact and transform one another over time. In short, then, current approaches view the roots of developmental and psychological disturbances in children as the result of complex interactions over the course of development between the biology of brain maturation and the multidimensional nature of experience (Belsky & de Haan, 2011; D'Onofrio, Rathouz, & Lahey, 2011; Reiss & Neiderhiser, 2000; Rutter et al., 1997).

The experience and the expression of psychopathology in children have cognitive, affective, physiological, and behavioral components; in light of this, many differing descriptions and definitions of dysfunctionality in children have been proposed. As we discuss in a later section, a common theme in defining child psychopathology has been "adaptational failure" in one or more of these components or in the ways in which these components are organized and integrated (Rutter & Sroufe, 2000; Sameroff, 2000). Adaptational failure may involve deviation from age-appropriate norms (Achenbach, 2001); exaggeration or diminishment of normal developmental expressions; interference in normal developmental progress; failure to master developmental tasks; failure to develop a specific function or regulatory mechanism; and/or the use of non-normative skills (e.g., rituals, dissociation) as a way of adapting to regulatory problems or traumatic experiences (Sroufe, 1997).

A multitude of etiological models and treatment approaches have been proposed to explain and remediate psychopathology in children. Unfortunately, most of these have yet to be substantiated or even adequately tested (Kazdin, 2000, 2001). These models and approaches have differed in their relative emphasis on certain causal mechanisms and constructs, often using very different terminology and concepts to describe seemingly similar child characteristics and behaviors. Although useful, many of these models have been based on what seem to be faulty premises concerning singular pathways of causal influence that do not capture the complexities of child psychopathology (Kazdin & Kagan, 1994).

In this regard, evolutionary models have emphasized the role of selection pressures operating on the human species over millions of years; biological paradigms have emphasized genetic mutations, neuroanatomy, and neurobiological mechanisms as factors contributing to psychopathology; psychodynamic models have focused on intrapsychic mechanisms, conflicts, and defenses;

attachment models have emphasized the importance of early relationships and the ways in which internal representations of these relationships provide the foundation for constructing working models of self, others, and relationships more generally; behavioral/reinforcement models have emphasized excessive, inadequate, or maladaptive reinforcement and/or learning histories; social learning models have emphasized the importance of observational learning, vicarious experience, and reciprocal social interactions; cognitive models generally focus on the child's distorted or deficient cognitive structures and processes; affective models have emphasized dysfunctional emotion-regulating mechanisms; and family systems models have conceptualized child psychopathology within a framework of intra- and intergenerational family systems and subsystems and have emphasized the structural and/or functional elements surrounding family relational difficulties.

The distinctiveness of each model mentioned above is in the relative importance it attaches to certain events and processes. However, it should be emphasized that despite these variations in the relative emphasis given to certain causes versus others, most models recognize the role of multiple interacting influences. For example, although they differ in emphasis, social learning and affective models both place importance on the role of symbolic representational processes in explaining childhood dysfunction.

There is a growing recognition of the need to integrate currently available models through intra- and interdisciplinary research efforts. Such integration generally requires looking beyond the emphasis of each single-cause theory to see what can be learned from other approaches, as well as a general openness to relating concepts and findings from diverse theories (cf. Arkowitz, 1992). Studies suggest that theoretical integration is becoming more common in psychopathology research (e.g., Beauchaine, 2001). Attachment theory has, for instance, been increasingly integrated with cognitive models (e.g., Ingram & Ritter, 2000). Theoretical integration is also apparent in studies combining proximal cognitive and interpersonal factors with distal variables, such as genetic markers of risk, the early home environment, and patterns of attachment (e.g., Caspi et al., 2003; Gibb, Beevers, & McGeary, 2013; Hayden, Klein, et al., 2010; Lara, Klein, & Kasch, 2000). The link between cognitive and neuropsychological functioning is likewise being tested more frequently (e.g., Nigg, Blaskey, Huang-Pollack, & Rappley, 2002). Thus researchers increasingly recognize the importance of combining theoretical approaches, and are accepting the monumental task of incorporating increased complexity into their research designs. The need for such integrative research approaches has important implications for training future developmental psychopathologists to be conversant in a broad array of research approaches and theories.

On a related note, interdisciplinary perspectives on child psychopathology mirror the considerable investment in children on the part of many different disciplines and professions. The study of the etiology and maintenance of psychopathology in children has been and continues to be the subject matter of psychology, medicine, psychiatry, education, and numerous other disciplines. Clearly, no one discipline has proprietary rights to the study of childhood disturbances, and each has tended to formulate child psychopathology in terms of its own unique perspective. Particularly relevant, in the context of this chapter, is that child psychopathology and normality in medicine and psychiatry have traditionally been conceptualized and defined categorically in terms of the presence or absence of a particular disorder or syndrome that is believed to exist "within the child." In contrast, psychology has more often conceptualized psychopathology–normality as representing extremes on a continuum or dimension of characteristics, and has also focused on the role of environmental influences that operate "outside the child." However, the boundaries between categories and dimensions, or between inner and outer conditions and causes, are arbitrarily drawn, and there is a continuing need to find workable ways of integrating the two different world views of psychiatry/medicine and psychology (Pickles & Angold, 2003; Richters & Cicchetti, 1993; Scotti & Morris, 2000; Shaffer, Lucas, & Richters, 1999).

Despite these ongoing issues in the field, the subsequent chapters in this volume attest to the substantial and rapid accrual of research on child psychopathology. This in turn has resulted in a rapidly expanding and changing knowledge base. Each chapter in this volume provides a comprehensive review of current research and theory for a specific form of child psychopathology, and a discussion of new developments and directions related to this disorder. In the remainder of this introductory chapter, we provide a discussion of the following: an overview of the significance and implications of child psychopathology; epidemiological considerations; key concepts in the field; approaches to the definition and conceptualization of childhood disorders; an overview of the developmental psycho-

pathology framework; predominant theories regarding etiology; and prevalent and recurrent conceptual and methodological issues that cut across the wide spectrum of disorders represented in this volume. Particular emphasis is given to concepts, methods, and strategies capturing the complexities, reciprocal influences, and divergent pathways that current models and research have identified as crucial for understanding child psychopathology.

SIGNIFICANCE OF CHILD PSYCHOPATHOLOGY

There has been and continues to be a great deal of misinformation and folklore concerning disorders of childhood. Many unsubstantiated theories have emerged in both the popular and scientific literatures. These have ranged from mid-19th-century views that overstimulation in the classroom causes insanity (see Makari, 1993), to mid-20th-century views that inadequate parenting causes autism (Bettelheim, 1967) or that chemical food additives are the primary cause of hyperactivity (Feingold, 1975). In addition, many of the constructs used to describe the characteristics and conditions of psychopathology in children have been globally and/or poorly defined (e.g., "adjustment problem," "emotional disturbance"). Despite the limitations, uncertainties, and definitional ambiguities that exist in the field, it is also evident that psychopathology during childhood represents a frequently occurring and significant societal concern that is gradually coming to the forefront of the political agenda.

Increasingly, researchers in the fields of child development, developmental psychopathology, child psychiatry, and clinical child psychology are considering the social policy implications of their work and striving to effect improvements in the identification of and services for youth with mental health needs (Cicchetti & Toth, 2000; Kazdin & Blase, 2011; Shonkoff, 2010; Shonkoff & Bales, 2011). For example, such work contributed to a recent report of the Surgeon General's office on suicide prevention, part of which focused on prevention of suicide in youth (U.S. Public Health Service, 2012). Such efforts are critical, given that public policies that promote early socioemotional well-being and reduce the conditions that lead to early child maltreatment may provide the foundation needed for later school success and positive peer and teacher relationships. Policy makers are generally not well acquainted with children's mental health concerns, or with the serious ramifications of early maladjustment (Nelson & Mann, 2011). Furthermore, public policy has not kept pace with advances in the field of child psychopathology (Zero to Three, 2012), especially with regard to recognizing how common and pervasive disorders of childhood are, or having an awareness of the benefits of early screening and intervention (Sices, 2007). Strategies to promote positive early development, as well as to prevent and treat early mental health problems, will require not only significant investment on the part of federal and local governments but an increased recognition that public policy should be shaped by empirical research. The need for policy to (1) support the training of individuals with the necessary expertise in children's mental health, and to (2) address the significant, ongoing obstacle faced by many parents of how to afford such expertise, has also been noted (Zero to Three, 2012).

The growing attention to children's mental health problems and competencies arises from a number of sources. First, many young people experience significant mental health problems that interfere with normal development and functioning. As many as one-third of children in the United States experience some type of difficulty (Costello, Mustillo, et al., 2003); this longitudinal study indicated that the risk of experiencing a psychiatric disorder by age 16 was much higher than previous estimates, derived from cross-sectional data, had indicated. Furthermore, this estimate probably underestimates the impact of psychopathology in youth, since it does not capture subclinical or undiagnosed disturbances that nevertheless place children at high risk for the later development of more severe clinical problems (e.g., Keenan et al., 2008). In addition, although not meeting formal diagnostic criteria, many subclinical conditions (e.g., depressed mood, eating problems) are associated with significant impairment in functioning (e.g., Angold, Costello, Farmer, Burns, & Erkanli, 1999; Lewinsohn, Striegel-Moore, & Seeley, 2000). Evidence gathered by the World Health Organization (WHO) suggests that by the year 2020, childhood neuropsychiatric disorders will rise by over 50% internationally to become one of the five most common causes of morbidity, mortality, and disability among children (U.S. Public Health Service, 2001b).

Second, a significant proportion of children do not grow out of their childhood difficulties, although the ways in which these difficulties are expressed change in dynamic ways over time (Masten & Cicchetti, 2010). Even when diagnosable psychopathology is not

evident at later ages, a child's failure to adjust during earlier developmental periods may still have a lasting negative impact on later family, occupational, and social adjustment. Furthermore, some forms of child psychopathology—for example, an early onset of antisocial patterns of behavior—are highly predictive of a host of negative outcomes later in life (e.g., Kim-Cohen et al., 2005).

Third, recent social changes and conditions may place children at increasing risk for the development of disorders, and also for the development of more severe problems at younger ages (Dupéré et al., 2009; Masten & Narayan, 2012). These social changes and conditions include multigenerational adversity in inner cities; chronic poverty in women and children; pressures of family breakup, single parenting, and homelessness; problems of the rural poor; direct and indirect exposure to traumatic events (e.g., terrorist attacks or school shootings); adjustment problems of children in immigrant families; difficulties of Native American children; and conditions associated with the impact of prematurity, HIV, cocaine, and alcohol on children's growth and development (McCall & Groark, 2000; Shonkoff & Phillips, 2000). In addition to sociocultural changes, medical advances associated with higher rates of fetal survival may also contribute to a greater number of children's showing serious behavior problems and learning disorders at a younger age.

Fourth, for a majority of children who experience mental health problems, these problems go untreated: Kataoka, Zhang, and Wells (2002) reported that of children identified as needing mental health services, only about 20% received such assistance. Rates of unmet need were even higher in ethnic minority groups and in children without insurance. Even when children are identified and receive help for their problems, this help may be less than optimal. For example, only about half of children with identified attention-deficit/hyperactivity disorder (ADHD) seen in real-world practice settings receive care that conforms to recommended treatment guidelines (Hoagwood, Kelleher, Feil, & Comer, 2000). The fact that so few children with mental health problems receive appropriate help is probably related to such factors as a lack of screening, inaccessibility, cost, a lack of perceived need on the part of parents, parental dissatisfaction with services, and the stigmatization and exclusion often experienced by these children and their families (Hinshaw, 2007; Hinshaw & Cicchetti, 2000). These and other factors have stimulated recent initiatives to identify children with unmet mental health needs (e.g., Jensen et al., 2011). Although empirically supported prevention and treatment programs for many childhood disorders have become increasing established in recent decades (Chorpita et al., 2011; Kazak et al., 2010), a pressing need remains for additional research on normative child development, developmental psychopathology, and the continued development and evaluation of prevention and intervention programs that are grounded in empirical evidence (Greenberg, Domitrovich, & Bumbarger, 2001; Kazdin, 2001; Rapport, 2001; Silverman & Hinshaw, 2008).[2]

Fifth, a majority of children with mental health problems who go unidentified and unassisted often end up in the criminal justice or mental health systems as young adults (Loeber & Farrington, 2000). They are at much greater risk for dropping out of school and of not being fully functional members of society in adulthood; this adds further to the costs of childhood disorders in terms of human suffering and financial burdens. For example, average costs of medical care for youngsters with ADHD are estimated to be double those for youngsters without ADHD (Leibson, Katusic, Barbaresi, Ransom, & O'Brien, 2001). Moreover, allowing just *one* youth to leave high school for a life of crime and drug abuse is estimated to cost society from $1.7 to $2.3 million or more (Cohen, 1998; Cohen & Piquero, 2009).

Finally, a significant number of children in North America experience maltreatment, and chronic maltreatment during childhood is associated with psychopathology in children and later in adults (Fergusson, Borden, & Horwood, 2008; Gunnar et al., 2006). Based on a review of the evidence, De Bellis (2001) has proposed that the psychobiological outcomes of abuse be viewed as "an environmentally induced complex developmental disorder" (p. 539). Although precise estimates of the rates of occurrence of maltreatment are difficult to obtain, due to the covert nature of the problem and other sampling and reporting biases (Cicchetti & Manly, 2001; Wekerle, Wolfe, Dunston, & Alldred, Chapter 16, this volume), the numbers appear to be large. Over 3.5 million suspected cases of child abuse and neglect are investigated each year by child protective service agencies, and about 1 million children in the United States were confirmed as victims of child maltreatment in 2010 (U.S. Department of Health and Human Services [USDHHS], 2011). It has been estimated that each year over 2,000 infants and young children die from abuse or neglect at the hands of their par-

ents or caregivers (USDHHS, 2011). Moreover, many reports of "accidental" injuries in children may be the result of unreported mistreatment by parents or siblings (Peterson & Brown, 1994). It would appear, then, that the total number of children who show adverse psychological and physical effects of maltreatment in North American society is staggering.

EPIDEMIOLOGICAL CONSIDERATIONS

Prevalence

Epidemiological studies seek to determine the prevalence and distribution of disorders and their correlates in particular populations of children who vary in age, sex, socioeconomic status (SES), ethnicity, or other characteristics (Costello & Angold, 2000). Although epidemiological studies of child psychopathology of the same scope as those of adult psychopathology (e.g., Kessler et al., 2005) have not been conducted, disorders of childhood appear to be common. Although reported rates vary widely from study to study, current best estimates are that 20–40% of all children worldwide have a clinically diagnosable disorder, and that many more children exhibit specific symptoms or subclinical problems (Belfer, 2008; Kessler et al., 2012; Merikangas, He, Brody, et al., 2010). Overall lifetime prevalence rates for childhood problems are on the order of 36% of all children (Costello, Mustillo, et al., 2003). Earlier studies also reported high rates of disorder; for example, Rutter, Tizard, and Whitmore (1970), in the classic Isle of Wight Study, found the overall rate of child psychiatric disorders to be 6–8% in 9- to 11-year-old children. Richman, Stevenson, and Graham (1975), in the London Epidemiological Study, found moderate to severe behavior problems for 7% of the population, with an additional 15% of children having mild problems. Boyle and colleagues (1987) and Offord and colleagues (1987), in the Ontario Child Health Study, reported that 19% of boys and 17% of girls had one or more disorders. Many other epidemiological studies have reported similar rates of prevalence (e.g., Brandenburg, Friedman, & Silver, 1990; Costello, Farmer, Angold, Burns, & Erkanli, 1997; Earls, 1980; Hewitt et al., 1997; Lapouse & Monk, 1958; MacFarlane, Allen, & Honzik, 1954; Shaffer et al., 1996; Verhulst & Koot, 1992; Werner, Bierman, & French, 1971). Perhaps the most consistent general conclusions to be drawn from these studies are that prevalence rates for childhood disorders are generally high, but that rates may vary with the nature of the disorder; the age, sex, SES, and ethnicity of the children; the criteria used to define the problem both concurrently and over time, the method used to gather information (e.g., interview, questionnaire); the informants (e.g., children, parents, teachers); sampling methods; and a host of other factors.

Age Differences

Bird, Gould, Yager, Staghezza, and Camino (1989) reported no significant age differences for children ages 4–16 years in the total number of *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) disorders diagnosed at each age. However, some studies have reported interactions among child age, number or type of problems, child sex, clinical status, and source of information (e.g., Simonoff et al., 1997). For example, Achenbach, Howell, Quay, and Conners (1991) found that externalizing problems showed a decline with age relative to internalizing problems, but only for those children who had been referred for treatment. More recently, using structured clinical interview data in a large sample of youth, Costello, Mustillo, and colleagues (2003) reported that the highest prevalence of disorder was found in children ages 9–10, with levels gradually falling through age 12 and then rising again throughout the adolescent years. The authors noted that this was likely due to the fact that the prevalence of many disorders of childhood (e.g., ADHD, separation anxiety disorder) decreases by age 12, while disorders of adolescence and adulthood (e.g., major depression) have not yet emerged. Merikangas, He, Burstein, and colleagues (2010) recently reported that 22% of adolescents had a disorder associated with severe impairment and/or distress in a nationally representative survey of adolescents ages 13–18.

These and other findings raise numerous questions concerning age differences in children's problem behaviors. Answers to even a seemingly simple question such as "Do problem behaviors decrease (or increase) with age?" are complicated by (1) a lack of uniform measures of behavior that can be used across a wide range of ages; (2) qualitative changes in the expression of behavior with development; (3) interactions between child age and sex; (4) the use of different informants across development; (5) the specific problem behavior(s) of interest; (6) the clinical status of the children being assessed; and (7) the use of different diagnostic criteria for children of different ages. Notwith-

standing these difficulties, both longitudinal and cross-sectional general population surveys are informative in depicting changes in the proportions of specific parent-, teacher-, or child-reported problem behaviors with age (e.g., "hyperactive," "argues," "cries"), as well as the manner in which the age changes vary as a function of problem type, child sex, and child clinical status. However, it should be emphasized that general age trends are based on group statistics, which may obscure the nonlinear and non-normative changes that often occur for individual children. In addition, general surveys do not provide information concerning the processes underlying age changes. Studies of change in individual children over time, and of the context in which this change occurs, are needed if such processes are to be understood.

Socioeconomic Status

Although most children treated for mental health problems are from the middle class, mental health problems are overrepresented among the very poor. It is estimated that 20% or more of children in North America are poor, and that as many children growing up in poverty are impaired to some degree in their social, behavioral, and academic functioning (McLeod & Nonnemaker, 2000). Lower-SES children have been reported to display more psychopathology and other problems than upper-SES children (e.g., McMahon & Luthar, 2007; Samaan, 2000). However, although the reported relationships between SES and child psychopathology are statistically significant, the effects are small and should be interpreted cautiously (Achenbach et al., 1991), as global estimates of SES tell us little about the multifarious processes through which SES and children's adaptive and maladaptive development are related (Schreier & Chen, 2013). Knowledge of such processes is needed to inform our understanding of disorders and to develop preventative efforts that target the appropriate mechanisms. For example, the effects of SES on aggression can be explained partly by stressful life events and by beliefs that reflect a tolerance or acceptance of aggression (Guerra, Tolan, Huesmann, Van Acker, & Eron, 1995). Other work suggests that the impact of SES on broader externalizing problems may be related to the reduced ability of impoverished parents to monitor their children (Costello, Compton, Keeler, & Angold, 2003). Further illustrating the complex interplay between risks, the environment that parents provide is also related to parental psychopathology, as in the case of adult ADHD, which is associated with low SES (Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1998); in such a case, parents confer both genetic and contextual risk on offspring, and this contextual risk emerges at least in part through gene–environment correlation (with the potential for "downward drift," such that disorder reduces economic opportunity, in the present case).

Thus associations between socioeconomic disadvantage and children's mental health derive from the fact that SES is a marker of many potential sources of negative influence (Bradley, Corwyn, McAdoo, & García Coll, 2001). Low SES is often characterized by low maternal education, a low level of employment, single-parent status, parental psychopathology, limited resources, and both chronic and acute negative life events (e.g., poor nutrition, exposure to violence), in addition to low income. Since overall indices of SES may include one or more of these variables in any given study, the relationship that is reported between SES and child psychopathology may vary as a function of the particular index used, as well as ethnic factors (McLeod & Nonnemaker, 2000). In short, SES is a marker of many factors that influence risk for child psychopathology, and the way in which this indicator is operationalized has an impact on its associations with childhood disorder.

Some research findings in child psychopathology are confounded by a failure to include SES in models. For example, although physically abused children show higher levels of externalizing problems than nonabused children (Mash, Johnston, & Kovitz, 1983), it is not clear that physical abuse and externalizing problems are associated when the effects of SES are controlled for (Cummings, Hennessy, Rabideau, & Cicchetti, 1994; Fergusson et al., 2008). The relationships among SES, maltreatment, and behavior disorders are further complicated by other findings that the effects of physical abuse on internalizing disorders may be independent of SES, whereas the effects of abuse on externalizing disorders may be dependent on SES-related conditions (Okun, Parker, & Levendosky, 1994).

Sex Differences

Although sex differences in the expression of psychopathology have been formally recognized since Freud's writings at the beginning of the 20th century, psychopathology in girls has historically received far less research attention than psychopathology in boys (Bell-

Dolan, Foster, & Mash, 2005; Rose & Rudolph, 2006). Until recently, many studies either have excluded girls from their samples entirely or have failed to examine whether relevant effects differed across the two sexes. For example, until fairly recently, there were relatively few studies of disruptive behavior disorders in girls (e.g., Moffitt, Caspi, Rutter & Silva, 2001; Silverthorn & Frick, 1999), probably because such disorders are more common in boys than in girls during childhood. Also contributing to this may be sampling biases (in which boys, who are more severely disruptive, are more likely to be referred and studied), as well as the fact that the inclusionary diagnostic criteria most commonly used are derived and validated largely from studies with boys (Frick & Nigg, 2012; Spitzer, Davies, & Barkley, 1990).

Research has confirmed that there are important differences in the prevalence, expression, accompanying disorders, underlying processes, outcomes, and developmental course of psychopathology in boys versus girls (Willcutt & Pennington, 2000a; Zahn-Waxler, Shirtcliff, & Marceau, 2008). ADHD, autism spectrum disorder, childhood conduct and oppositional disorders, and learning and communication disorders are all more common in boys than girls, whereas the opposite is true for most anxiety disorders, adolescent depression, and eating disorders (Copeland et al., 2011; Rutter et al., 2004). Relatedly, boys exhibit higher levels of externalizing symptoms than girls do throughout childhood and early adolescence, whereas girls and boys are comparable in terms of internalizing symptoms in early childhood, with girls' levels of these symptoms increasing more rapidly than boys during adolescence (e.g., Bongers, Koot, van der Ende, & Verhulst, 2003). Although these sex differences are well established, their meaning is poorly understood (Martel, 2013). For example, it is difficult to determine whether observed sex differences are functions of referral or reporting biases, the way in which disorders are currently defined, differences in the expression of a disorder (e.g., direct vs. indirect aggressive behavior), sex differences in the genetic penetrance of disorders, sexual selection effects/evolutionary processes, or sex differences in biological characteristics and environmental susceptibilities. All are possible, and there is a need for research into the processes underlying observed differences. Clearly the mechanisms and causes of sex differences may vary for different disorders (e.g., ADHD vs. depression), or for the same disorder at different ages (e.g., child vs. adolescent obsessive–compulsive disorder or early- vs. late-onset conduct disorder). For example, Moffitt and Caspi (2001) found that sex differences in life-course-persistent antisocial behavior were attributable to differences in rates of risk factors for early-onset, persistent forms of such behaviors, such as hyperactivity, poor parenting, and neuropsychological dysfunction, which may disproportionately affect boys compared to girls.

Early research into sex differences focused mainly on descriptive comparisons of the frequencies of different problems for boys versus girls at different ages. In general, differences in problem behaviors between the sexes are small in children of preschool age or younger (e.g., Briggs-Gowan, Carter, Skuban, & Horwitz, 2001; Gadow, Sprafkin, & Nolan, 2001), but become increasingly common with age. For example, Weisz and Suwanlert (1989) studied children in the United States and Thailand, and found that boys were rated higher than girls on every problem for which there was a significant sex difference—including total problems, undercontrolled problems, overcontrolled problems, and culture-specific problems. Across cultures, boys have been found to display more fighting, impulsivity, and other uncontrolled behaviors than girls (Olweus, 1979). It has been found that boys show greater difficulties than girls during early and middle childhood, particularly with respect to ADHD and disruptive behavior disorders (Costello, Mustillo, et al., 2003). Girls' problems may increase during adolescence, with higher prevalence rates for depression and dysphoric mood from midadolescence through adulthood. For example, conduct disorder and ADHD have been found to be more frequent in 12- to 16-year-old boys than girls, whereas emotional problems have been found to be more frequent for girls than boys in this age group (Boyle et al., 1987; Offord et al., 1987).

However, not all studies have reported significant sex differences in overall rates of problem behavior (e.g., Achenbach & Edelbrock, 1981; Velez, Johnson, & Cohen, 1989), and even when significant overall sex differences have been found, they tend to be small and to account for only a small proportion of the variance. It has also been found that although there is a much larger predominance of externalizing problems in boys and of internalizing problems in adolescent girls in samples of children who are referred for treatment, sex differences in externalizing versus internalizing problems are minimal in nonreferred samples of children (Achenbach et al., 1991). Furthermore, there may be cohort effects on sex differences in some forms of psychopathology.

For example, the sex difference in substance use disorders, which historically consisted of higher rates of these disorders in boys compared to girls, appears to be disappearing in more recent cohorts due to increased substance use by girls (Johnston, O'Malley, Bachman, & Schulenberg, 2011).

Comparisons of the behavioral and emotional problems in boys versus girls over time can provide useful information about sex-related characteristics. However, taken in isolation, such global comparisons do not address possible qualitative differences in (1) expressions of psychopathology in boys versus girls; (2) the processes underlying these expressions; (3) the long-term consequences of certain behaviors for boys versus girls; and/or (4) the impact of certain environmental events on boys versus girls (Zahn-Waxler et al., 2008). As noted by Hops (1995), it seems likely that "the pathways from childhood to adolescence and adult pathology are age and gender specific and that these differences may be the result of different social contexts that nurture the development of health or pathology for female and male individuals" (p. 428). In addition to differential socialization practices, there are likely to be differences in the expression and outcome of psychopathology in boys versus girls as a function of biologically based differences. For example, in a study of the psychophysiology of disruptive behavior in boys versus girls, Zahn-Waxler, Cole, Welsh, and Fox (1995) found that disruptive girls showed high electrodermal responding relative to disruptive boys and were also highly activated by a sadness mood induction. These investigators suggested that girls' disruptive behavior may be more closely connected than boys' disruptive behavior to experiences of anxiety. Other research has found that increases in depression in females during adolescence are related mostly to accompanying changes in levels of estrogen and testosterone (Angold, Costello, Erkanli, & Worthman, 1999). It is also possible that for some disorders (e.g., ADHD), girls may require a higher genetic loading for the disorders than boys before the disorders are likely to express themselves (Rhee, Waldman, Hay, & Levy, 1999).

There may also be differences in the processes underlying the expression of psychopathology and distress in boys versus girls (Chaplin & Aldao, 2013; Kistner, 2009; Rutter, Caspi, & Moffitt, 2003). For example, a slower rate of biological maturation (Zahn-Waxler, Crick, Shirtcliff, & Woods, 2006; Zahn-Waxler et al., 2008), as well as sex differences in temperamental variables (Else-Quest, Hyde, & Goldsmith, 2006; Frick & Morris, 2004; Olino, Durbin, Klein, Hayden, & Dyson, 2013) may provide explanatory mechanisms for the higher rates of conduct problems in boys versus girls. In addition, depression in adolescent females has been found to be strongly associated with maternal depression, whereas a lack of supportive early care appears to be more strongly associated with depression in adolescent males (Duggal, Carlson, Sroufe, & Egeland, 2001). It has also been found that the types of child-rearing environments predicting resilience to adversity may differ for boys and girls. Resilience in boys is associated with households in which there is a male model (e.g., father, grandfather, older sibling), structure, rules, and some encouragement of emotional expressiveness. In contrast, resilient girls come from households that combine risk taking and independence with support from a female caregiver (e.g., mother, grandmother, older sister) (Werner, 1995). With respect to future goals for this specific aspect of research, the role of paternal psychopathology in offspring psychopathology risk, and whether its impact differs for boys versus girls, has not been explored to the extent it should (Connell & Goodman, 2002), given its known impact on other factors that shape child outcomes (e.g., paternal caregiving; Wilson & Durbin, 2010).

Zahn-Waxler and colleagues (2008) refer to the "gender paradox of comorbidities," which is that although the prevalence of disruptive behavior is lower in females than in males, the risk of comorbid conditions such as anxiety is higher in female samples. In explaining this paradox, these authors suggest that girls' heightened level of interpersonal sensitivity, caring, and empathy may be a protective factor with respect to the development of antisocial behavior. At the same time, girls' heightened sensitivity to the plight of others, and their reluctance to assert their own needs in situations involving conflict and distress, may elevate their risk for the development of internalizing problems. However, the relations between gender and comorbidity are likely to vary with the disorders under consideration, the age of a child, the source of referral, and other factors. For example, in contrast to Zahn-Waxler and colleagues (1995), Biederman and colleagues (2002) found that girls with ADHD had a significantly *lower* rate of comorbid major depression than did boys with ADHD. Martel (2013) has posited that sex differences such as these may have emerged via sexual selection processes related to the enhanced survival value or impact on mating opportunities linked to the biological substrates of these conditions.

Although findings relating to sex differences and child psychopathology are complex, inconsistent, and frequently difficult to interpret, the cumulative findings from research strongly indicate that the effects of gender are critical to understanding the expression and course of most childhood disorders (Bell-Dolan et al., 2005; Zahn-Waxler et al., 2008). It is particularly important to understand the processes and mechanisms underlying these gender effects, and to recognize that biological influences and differential socialization practices are likely to interact throughout development in accounting for any differences between the sexes that are found.

Rural versus Urban Differences

Although there is a general belief that rates of child behavior disorders are higher in urban than in rural areas, research findings in support of this view are weak and/or inconsistent. Findings from older studies of the Isle of Wight, Inner London Borough, and Ontario Child Health Studies reveal prevalence rates of problem behavior that were higher for urban than rural children (Offord et al., 1987; Rutter, 1981). On the other hand, in a cross-cultural investigation, Weisz and Suwanlert (1991) found few differences in parent or teacher ratings of child problems as a function of rural versus urban status in either of the cultures that were studied (United States and Thailand). In a detailed analysis that controlled for the effects of SES and ethnicity and also looked at gradations of urbanization, Achenbach and colleagues (1991) found few differences in children's behavior problems or competencies as a function of rural-versus-urban status, although there was a significant but very small effect indicating higher delinquency scores for children in urban environments. These investigators concluded that earlier findings of higher rates of problem behavior in urban than in rural areas "may have reflected the tendency to combine areas of intermediate urbanization with large urban areas for comparison with rural areas as well as a possible lack of control for demographic differences" (p. 86). Even in studies in which rural versus urban differences have been found, for the most part these differences were associated with economic and cultural differences between sites, and not with urbanization per se (Zahner, Jacobs, Freeman, & Trainor, 1993). Further complicating this issue is the possibility that the effects of urbanicity on psychopathology likely vary depending on disorder. For example, van Son, van Hoeken, Bartelds, van Furth, and Hoek (2006) found that rates of bulimia nervosa were higher in urban areas, whereas rates of anorexia nervosa did not differ depending on urbanization. Intriguingly, some of the effects of urbanicity on psychopathology may operate via gene–environment interaction; for example, environmental conditions appear to moderate the relative contribution of genetic effects on externalizing forms of psychopathology (Legrand, Keys, McGue, Iacono, & Krueger, 2008).

Ethnicity and Culture

Ethnicity

Numerous terms have been used to describe ethnic influences. These include "ethnicity," "race," "ethnic identity," "ethnic orientation," "acculturation," "bicultural orientation," and "culture." As Foster and Martinez (1995) have pointed out, there is a need to recognize the diversity of terminology that has been used in describing ethnicity, and the fact that these terms refer to related but different things. Despite the growing ethnic diversity of the North American population, ethnic representation in research studies and the study of ethnicity-related issues more generally have received less attention in studies of child psychopathology (García Coll, Akerman, & Cicchetti, 2000; U.S. Public Health Service, 2001a). Until recently, research into child psychopathology has generally been insensitive to possible differences in prevalence, age of onset, developmental course, and risk factors related to ethnicity (Yasui & Dishion, 2007), as well as to the considerable heterogeneity within specific ethnic groups (Murry, Bynum, Brody, Willert, & Stephens, 2001; Serafica & Vargas, 2006). In addition, few studies have compared ethnic groups while controlling for other important variables, such as SES, sex, age, and geographic region. Some recent studies suggest that children from minority groups are overrepresented in certain disorders, such as substance use disorders (Nguyen, Huang, Arganza, & Liao, 2007). Overall, studies with much larger national samples that included European American, African American, and Hispanic American children have reported either no or very small differences related to race or ethnicity when SES, sex, age, and referral status were controlled for (Achenbach & Edelbrock, 1981; Achenbach et al., 1991; Lahey et al., 1995). Thus, although externalizing problems have been reported more frequently among African American children (McLaughlin, Hilt, & Nolen-Hoeksema,

2007), this finding is probably an artifact related to SES. Unfortunately, African American and Hispanic American children are much less likely to receive specialty mental health services or psychotropic medications (García Coll & Garrido, 2000). Native American youth appear to have elevated rates of problem behaviors, including substance abuse and suicide (Whitbeck, Yu, Johnson, Hoyt, & Walls, 2008). Ethnicity has not been found to be strongly associated with risk for eating disorders (Leon, Fulkerson, Perry, & Early-Zald, 1995), although differences between European Americans and other groups have been reported for such subclinical eating disturbances as dietary restraint, ideal body shape, and body dissatisfaction (Wildes & Emery, 2001). More research is needed in which potentially important third variables (e.g., SES) are adequately addressed, but these and other findings suggest that the effects of ethnicity are likely to vary with the problem under consideration and its severity.

As is the case for SES and sex differences, global comparisons of the prevalence of different types of problems for different ethnic groups are not likely to be very revealing. On the other hand, studies into the processes affecting the form, associated factors, and outcomes of different disorders for various ethnic groups hold promise for increasing our understanding of the relationship between ethnicity and child psychopathology (e.g., Bird et al., 2001; Bradley, Corwyn, Burchinal, McAdoo, & García Coll, 2001).

Culture

The values, beliefs, and practices that characterize a particular ethnocultural group contribute to the development and expression of childhood distress and dysfunction, which in turn are organized into categories through cultural processes that further influence their development and expression (Achenbach & Rescorla, 2007; Harkness & Super, 2000; Wong & Ollendick, 2001). Through shared views about causality and intervention, culture also structures the way in which people and institutions react to a child's problems. Since the meaning of children's social behavior is influenced by cultural beliefs and values, it is not surprising that the form, frequency, and predictive significance of different forms of child psychopathology vary across cultures, or that cultural attitudes influence diagnostic and referral practices (Lambert et al., 1992). For example, shyness and oversensitivity in children have been found to be associated with peer rejection and social maladjustment in Western cultures, but with leadership, school competence, and academic achievement in Chinese children in Shanghai (Chen, Rubin, & Li, 1995). Similarly, Lambert, Weisz, and Knight (1989) found that overcontrolled problems were reported significantly more often for Jamaican than for American youngsters—a finding consistent with Afro-British Jamaican cultural attitudes and practices that discourage child aggression and other undercontrolled behavior, and that foster inhibition and other overcontrolled behavior.

Weisz and Sigman (1993), using parent reports of behavioral and emotional problems in 11- to 15-year-old children from Kenya, Thailand, and the United States, found that Kenyan children were rated particularly high on overcontrolled problems (e.g., fears, feelings of guilt, somatic concerns), due primarily to numerous reports of somatic problems. In this mixed-race sample, whites were rated particularly high on undercontrolled problems (e.g., "arguing," "disobedient at home," "cruel to others"). Weisz and Suwanlert (1987) compared 6- to 11-year-old children in the Buddhist-oriented, emotionally controlled culture of Thailand with American 6- to 11-year-olds. Parent reports revealed Thai–U.S. differences in 54 problem behaviors, most of which were modest in magnitude. Thai children were rated higher than American children on problems involving overcontrolled behaviors such as anxiety and depression, whereas American children were rated higher than Thai children on undercontrolled behaviors such as disobedience and fighting.

Weisz and Suwanlert (1991) compared ratings of behavior and emotional problems of 2- to 9-year-old children in Thailand and the United States. Parents and teachers in Thailand rated both overcontrolled and undercontrolled problems as less serious, less worrisome, less likely to reflect personality traits, and more likely to improve with time. These findings suggest that there may be cultural differences in the meanings ascribed to problem behaviors across cultures.

Findings from these and other studies suggest that the expression of, and tolerance for, many child behavioral and emotional disturbances are related to social and cultural values. The processes that mediate this relationship are in need of further investigation. In this regard, it is important that the results of research on child psychopathology not be generalized from one culture to another, unless there is support for doing so. There is some support for the notion that some processes—for example, those involved in emotion regulation and its

relation to social competence—may be similar across diverse cultures (Eisenberg, Pidada, & Liew, 2001). The rates of expression of some disorders, particularly those with a strong neurobiological basis (e.g., ADHD, autism spectrum disorder), may be less susceptible to cultural influences than others. However, even so, social and cultural beliefs and values are likely to influence the meaning given to these behaviors, the ways in which they are responded to, their forms of expression, their outcomes, and responses to intervention (Castro, Barrera, & Holleran-Steiker, 2010).

An important distinction to be made with respect to cross-cultural comparisons is whether there are substantive differences in the rates of a disorder, or differences in the raters' perceptions of these problems. For example, Weisz and Suwanlert (1989) compared the teacher-reported behavioral/emotional problems of Thai and U.S. children (ages 6–11 years). It was found that Thai teachers were confronted with students who were more prone to behavioral and emotional problems at school than were teachers in the United States, but that they applied different judgments to the behaviors they observed. Similarly, cultural factors are known to influence not only informal labeling processes but formal diagnostic practices as well. For example, reported prevalence rates of ADHD in Great Britain are much lower than in the United States because of differences in the way in which diagnostic criteria for ADHD are applied in the two countries. Such differences in diagnostic practices may lead to spurious differences in reported prevalence rates for different forms of child psychopathology across cultures.

Cross-cultural research on child psychopathology would suggest that the expression and experience of mental disorders in children is not universal (Fisman & Fisman, 1999). Patterns of onset and duration of illness and the nature and relationship among specific symptoms vary from culture to culture, and across ethnic groups within cultures (Achenbach, 2001; Hoagwood & Jensen, 1997; Yasui & Dishion, 2007). However, few studies have compared the attitudes, behaviors, and biological and psychological processes of children with mental disorders across different cultures. Such information is needed to understand how varying social experiences and contexts influence the expression, course, and outcome of different disorders across cultures. Greater social connectedness and support in more traditional cultures and greater access to resources and opportunities in industrialized societies are examples of mechanisms that may alter outcomes across cultures. Sensitivity to the role of cultural influences in child psychopathology has increased (Evans & Lee, 1998; Lopez & Guarnaccia, 2000), and is likely to continue to do so as globalization and rapid cultural change become increasingly more common (García Coll et al., 2000).

KEY CONCEPTS IN CHILD PSYCHOPATHOLOGY

Several recurrent and overlapping issues have characterized the study of psychopathology in children (Cicchetti & Toth, 2009; Rutter & Sroufe, 2000). A number of these are highlighted in this section, including (1) difficulties in conceptualizing psychopathology and normality; (2) the need to consider healthy functioning and adjustment; (3) questions concerning developmental continuities and discontinuities; (4) the concept of developmental pathways; (5) the notions of risk and resilience; (6) the identification of protective and vulnerability factors; and (7) the role of contextual influences.

Psychopathology versus Normality

The attempt to establish boundaries between what constitutes abnormal and normal functioning is an arbitrary process at best (see Achenbach, 1997), although this does not necessarily imply that such boundaries are meaningless, if they are informative with respect to impairment and other clinically significant factors. Traditional approaches to mental disorders in children have emphasized concepts such as symptoms, diagnosis, illness, and treatment; by doing so, they have strongly influenced the way we think about child psychopathology and related questions (Richters & Cicchetti, 1993). Childhood disorders have most commonly been conceptualized in terms of deviancies involving breakdowns in adaptive functioning, statistical deviation, unexpected distress or disability, and/or biological impairment.

Wakefield (1992, 1997, 1999b, 2010) has proposed an overarching concept of mental disorder as "harmful dysfunction." This concept encompasses a child's physical and mental functioning, and includes both value- and science-based criteria. In the context of child psychopathology, a child's condition is viewed as a disorder only if (1) it causes harm or deprivation of benefit to the child, as judged by social norms; and (2) it results from the failure of some internal mechanism to perform its natural function (e.g., "an effect

that is part of the evolutionary explanation of the existence and structure of the mechanism"; Wakefield, 1992, p. 384). This view of mental disorder focuses attention on evolved adaptations or internal functional mechanisms—for example, executive functions in the context of self-regulation (Barkley, 2001). Nevertheless, as Richters and Cicchetti (1993) have pointed out, this view only identifies the decisions that need to be made in defining mental disorders; it does not specify *how* such decisions are to be made.

As is the case for most definitions of mental disorder that have been proposed, questions related to defining the boundaries between normal and abnormal, understanding the differences between normal variability and dysfunction, defining what constitute "harmful conditions," linking dysfunctions causally with these conditions, and circumscribing the domain of "natural" or of other proposed mechanisms are matters of considerable controversy (Hudziak, Achenbach, Althoff, & Pine, 2007; Lilienfeld & Marino, 1995).[3] Categories of mental disorder stem from human-made linguistic distinctions and abstractions, and boundaries between what constitutes normal and abnormal conditions, or between different abnormal conditions, are not easily drawn. Although it may sometimes appear that efforts to categorize mental disorders are "carving nature at its joints," whether or not such "joints" actually exist is open to debate (e.g., Angold & Costello, 2009; Cantor, Smith, French, & Mezzich, 1980; Lilienfeld & Marino, 1995). However, clear distinctions do not necessarily need to exist for categorical distinctions to have utility. For instance, there is no joint at which one can carve day from night, although distinguishing the two has proven incredibly useful to humans in going about their social discourse and engagements. Likewise, although the threshold for determining disorder from high levels of symptoms may be fuzzy, it could be stipulated as being at that point along a dimension where impairment in a major, culturally universal life activity befalls the majority of people at or exceeding that point. Thus, despite the lack of clear boundaries between what is normal and abnormal, categorical distinctions are still useful as long as they adequately predict which children will be most likely to benefit from access to special education, treatment, or disability status.

Healthy Functioning

The study of psychopathology in children requires concomitant attention to adaptive developmental processes for several reasons. First, judgments of deviancy require knowledge of normative developmental functioning, both with respect to a child's performance relative to same-age peers and with respect to the child's own baseline of development. Second, maladaptation and adaptation often represent two sides of the same coin, in that dysfunction in a particular domain of development (e.g., the occurrence of inappropriate behaviors) is usually accompanied by a failure to meet developmental tasks and expectations in the same domain (e.g., the nonoccurrence of appropriate behaviors). It is important to point out, however, that adaptation should not be equated with the mere absence of psychopathology, nor should the converse be assumed (i.e., that symptoms can be equated with maladaptation). With respect to the former, Kendall and colleagues (Kendall, Marrs-Garcia, Nath, & Sheldrick, 1999; Kendall & Sheldrick, 2000), contend that it is important to use normative comparisons to evaluate treatment outcome; they suggest that improvement involves falling within a certain range of healthy functioning, in addition to decreased symptoms. Moreover, adaptation involves the presence and development of psychological, physical, interpersonal, and intellectual resources (see Fredrickson, 2001). With respect to the latter point, symptoms and impairment tend to be only moderately correlated, suggesting that for some children, symptoms do not have a pervasive negative impact on important life domains (Barkley, 2012a; Gordon et al., 2006).

Third, in addition to the specific problems that lead to referral and diagnosis, disturbed children are likely to show impairments in other areas of adaptive functioning. For example, in addition to their core symptoms of hyperactivity/impulsivity and inattention, children with ADHD typically show lower-than-average levels of functioning in their socialization, communication, and activities of daily living (e.g., Stein, Szumowski, Blondis, & Roizen, 1995). Fourth, most children with specific disorders are known to cope effectively in some areas of their lives. Understanding a child's strengths informs our knowledge of the child's disorder and provides a basis for the development of effective treatment strategies. Fifth, children move between pathological and nonpathological forms of functioning over the course of their development. Individual children may have their "ups and downs" in problem type and frequency over time. Sixth, many child behaviors that are not classifiable as deviant at a particular point in time may nevertheless represent less extreme expressions or compensations of an already existing disorder

or early expressions of a later progression to deviant extremes as development continues (Adelman, 1995). Finally, no theory of a childhood disorder is complete if it cannot be linked with a theory of how the underlying normal abilities develop and what factors go awry to produce the disordered state. Therefore, understanding child psychopathology requires that we also attend to these less extreme forms of difficulty and develop more complete models of the normal developmental processes underlying the psychopathology.

For these and other reasons to be discussed, the study of child psychopathology requires an understanding of both abnormal and healthy functioning (Cicchetti, 2006). As noted by Cicchetti and Richters (1993), "it is only through the joint consideration of adaptive and maladaptive processes within the individual that it becomes possible to speak in meaningful terms about the existence, nature, and boundaries of the underlying psychopathology" (p. 335). To date, far greater attention has been devoted to the description and classification of psychopathology in children than to healthy child functioning; to nonpathological psychosocial problems related to emotional upset, misbehavior, and learning; or to factors that promote the successful resolution of developmental tasks (Adelman, 1995; Sonuga-Barke, 1998). In light of this imbalance, there is a need for studies of normal developmental processes (Lewis, 2000), for investigations of normative and representative community samples of children (Ialongo, Kellam, & Poduska, 2000; Kazdin, 1989), and for studies of "resilient" children who show normal development in the face of adversity (Masten & Cicchetti, 2010).

Developmental Continuities and Discontinuities

A central issue for theory and research in child psychopathology concerns the continuity of disorders identified from one time to another and the relationship between child, adolescent, and adult disorders (Caspi, 2000; Rutter, Kim-Cohen, & Maughan, 2006; Schulenberg, Sameroff, & Cicchetti, 2004). Some childhood disorders, such as intellectual disability and autism spectrum disorder, are typically chronic conditions that will persist throughout childhood and into adulthood. Other disorders, such as functional enuresis and encopresis, occur during childhood and only rarely manifest themselves in adults (Walker, 2003). However, most disorders (e.g., mood disorders, schizophrenia, generalized anxiety disorder) are expressed, albeit in modified forms, in both childhood and adulthood and exhibit varying degrees of continuity over time. Evidence in support of the continuity between child and adult disorders is equivocal and depends on a number of methodological factors related to research design, assessment instruments, the nature of the study sample, and the type and severity of the disorder (Garber, 1984). In general, the literature suggests that child psychopathology is continuous with adult disorders for some, but not all, problems. As we discuss below, there is evidence that appears to favor the stability of externalizing problems over internalizing problems. However, previous findings may reflect the severity and pervasiveness of the disorders assessed, referral biases, and the fact that longitudinal investigations of children with internalizing and other disorders are just beginning to emerge. For example, recent longitudinal studies have found that anxiety disorders in childhood predict a range of psychiatric disorders in adolescence (e.g., Bittner et al., 2007). In another report, early-onset bulimia nervosa was associated with a 9-fold increase in risk for late-adolescent bulimia nervosa and a 20-fold increase in risk for adult bulimia nervosa (Kotler, Cohen, Davies, Pine, & Walsh, 2001).

The possible mechanisms underlying the relationships between early maladaptation and later disordered behavior are numerous and can operate in both direct and indirect ways (Garber, 1984; Rutter, 1994a; Sroufe & Rutter, 1984). Some examples of *direct* relationships between early and later difficulties include (1) the development of a disorder during infancy or childhood, which then persists over time; (2) experiences that alter an infant's or child's physical status (e.g., neural plasticity), which in turn influences later functioning (Courchesne, Chisum, & Townsend, 1994; Johnson, 1999; Nelson, 2000); and (3) the acquisition of early patterns of responding (e.g., compulsive compliance, dissociation) that may be adaptive in light of a child's current developmental level and circumstances, but may result in later psychopathology when circumstances change and new developmental challenges arise.

Some examples of *indirect* associations between child and adult psychopathology may involve early predispositions that eventually interact with environmental experiences (e.g., stressors), the combination of which leads to dysfunction. For example, Egeland and Hiester (1995) found that the impact of day care on disadvantaged high-risk children at 42 months of age was related to the children's attachment quality at 12 months of age, with securely attached children more likely to be negatively affected by early out-of-home

care. Other examples of indirect links between child and adult disturbance include (1) experiences (e.g., peer rejection) that contribute to an altered sense of self-esteem (DuBois & Tevendale, 1999), or that create a negative cognitive set, which then leads to later difficulties; and (2) experiences providing various opportunities or obstacles that then lead to the selection of particular environmental conditions, and by doing so guide a child's course of development (Rutter, 1987; Sroufe & Rutter, 1984).

Research efforts have focused not only on the continuities and discontinuities in childhood disorders, but also on the identification of factors that predict them. One factor that has been studied in the context of conduct disorder is age of onset, with early onset usually viewed as the occurrence of conduct disorder symptoms prior to age 10 years (American Psychiatric Association [APA], 2013b). It has been found that early onset of conduct disorder symptoms is associated with higher rates and more serious antisocial acts over a longer period of time for both boys and girls (Lavigne et al., 2001). However, there may be different subgroups of children with an early onset, and dispositional and psychosocial variables that are present prior to and following onset may influence the seriousness and chronicity more than age of onset per se does (Frick & Viding, 2009; Tolan & Thomas, 1995). A question that needs to be addressed is this: Does early age of onset operate in a causal fashion for later problems, and if so, how? Another issue is whether the causal processes that are associated with an early onset of a disorder (e.g., depression) are different from those that serve to maintain the disorder. Even then, the specification of an age of onset need not be made so precisely that it creates a false distinction that only valid cases meet this precise threshold, as may have happened with ADHD (see Nigg & Barkley, Chapter 2, this volume). Such efforts to impose precision where none exists may have backfired by hampering studies of teens and adults having the same disorder who cannot adequately recall such a precise onset, and by presuming that cases having qualitatively identical symptoms and impairments but later onsets are invalid instances of a disorder.

Although research supports the notion of continuity of disorders, it does not support the continuity of identical symptoms over time (i.e., "homotypic correspondence"). Continuity over time for patterns of behavior rather than for specific symptoms is the norm. For example, although externalizing disorders in boys are stable over time, the ways in which these behavioral patterns are expressed are likely to change dramatically over the course of development (Olweus, 1979). Even with wide fluctuations in the expression of behavior over time, "children may show consistency in their general adaptive or maladaptive pattern of organizing their experiences and interacting with the environment" (Garber, 1984, p. 34). Several research findings can be used to illustrate this notion of consistent "patterns of organization." For example, early, heightened levels of behavioral inhibition may affect later adjustment by influencing the way in which a child adapts to new and unfamiliar situations and the ensuing person–environment interactions over time (Kagan, 1994a). Another example of a consistent pattern of organization involves early attachment quality and the development of internal working models that children carry with them into their later relationships (Bowlby, 1988; Goldberg, 1991). Internal working models of self and relationships may remain relatively stable over time, at the same time that the behavioral expressions of these internal models change with development. From a neuroscientific perspective, Pennington and Ozonoff (1991) argue that certain genes and neural systems also play a significant predisposing role in influencing the continuity of psychopathology, and that the "discontinuities at one level of analyses—that of observable behavior—may mask continuities at deeper levels of analysis; those concerned with the mechanisms underlying observable behavior" (p. 117).

Given that developmental continuity is reflected in general patterns of organization over time rather than in isolated behaviors or symptoms, the relationships between early adaptation and later psychopathology are not likely to be direct or uncomplicated. The connections between psychopathology in children and adults are marked by *both* continuities and discontinuities. The degree of continuity–discontinuity will vary as a function of changing environmental circumstances and transactions between a child and the environment that affect the child's developmental trajectory.

Developmental Pathways

The concept of "developmental pathways" is crucial for understanding continuities and discontinuities in psychopathology. Such pathways are not directly observable, but function as metaphors that are inferred from repeated assessments of individual children over time and used as a framework for synthesis and integration (Loeber, 1991; Pickles & Hill, 2006). A pathway, ac-

cording to Loeber (1991), "defines the sequence and timing of behavioral continuities and transformations and, ideally, summarizes the probabilistic relationships between successive behaviors" (p. 98). In attempting to identify developmental pathways as either "deviant" or "normal," it is important to recognize that (1) different pathways may lead to similar expressions of psychopathology (i.e., "equifinality"); and (2) similar initial pathways may result in different forms of dysfunction (i.e., "multifinality"), depending on the organization of the larger system in which they occur (Cicchetti & Rogosch, 1996; Lewis, 2000; Loeber, 1991).

Research findings related to child maltreatment provide an example of a developmental pathway to maladaptive outcomes, with the important qualification that most children who are abused do not exhibit these negative outcomes. The question of why some children seem particularly susceptible to the impact of abuse has led to the search for susceptibility factors, such as child genetic markers (see Wekerle et al., Chapter 16, this volume). However, it is known that physically abused children are more likely to develop insecure attachments, to view interpersonal relationships as coercive and threatening, to become vigilant and selectively attend to hostile cues, to classify others instantly as threatening or nonthreatening, and to acquire aggressive behavioral strategies for solving interpersonal problems (see Cicchetti & Manly, 2001). These children bring representational models to peer relationships that are negative, conflictual, and unpredictable. They process social information in a biased and deviant manner, and develop problems with peer relationships that involve social withdrawal, unpopularity, and overt social rejection by peers (Dodge, Pettit, & Bates, 1994). In another example of a developmental pathway, the diagnosis of conduct disorder typically precedes the initiation of use of various substances, and this use in turn precedes the diagnosis of alcohol dependence in adolescents (Kuperman et al., 2001). Tragically, this can, in turn, exacerbate risk for persistant antisocial behavior by virtue of the reciprocal influences of alcohol dependence on antisocial behavior and vice versa (Barkley, Fischer, Smallish, & Fletcher, 2004).

The systematic delineation of developmental pathways not only offers several advantages for the study of the etiology and outcomes of childhood disorders, but may also suggest strategies for intervention. Loeber (1991, p. 99) describes these advantages as "attempts to capture the changing manifestations and variable phenotype of a given disorder" over time. In this way, the study of developmental pathways includes etiological considerations, the assessment of comorbidities as they accrue over time, and a sensitivity to diverse outcomes (e.g., White, Bates, & Buyske, 2001).

Risk and Resilience

Previous studies of child psychopathology focused on elucidating the developmental pathways for deviancy and maladjustment, to the relative exclusion of those for competency and adjustment (but see, for exceptions, Luthar, 1993; Rutter, 1985, 1987, 1994b; Rutter & Rutter, 1993). However, a significant number of children who are at risk do *not* develop later problems. There is a growing recognition of the need to examine not only risk factors, but also those conditions that protect vulnerable children from dysfunction and lead to successful adaptations despite adversity (Cicchetti & Garmezy, 1993; Masten & Wright, 2010).

"Resilience," which refers to successful adaptation in children who experience significant adversity, has now received a good deal of attention (Luthar, Cicchetti, & Becker, 2000). Early patterns of adaptation influence later adjustment in complex and reciprocal ways. Adverse conditions, early struggles to adapt, and failure to meet developmental tasks do not inevitably lead to negative outcomes. Rather, many factors can provide turning points whereby success in a particular developmental task (e.g., educational advances, peer relationships) shifts a child's course onto a more adaptive trajectory. Conversely, numerous events and circumstances, and underlying dynamic biological systems, may shape a child's developmental trajectory toward maladaptation (e.g., a dysfunctional home environment, peer rejection, difficulties in school, parental psychopathology, intergenerational conflict, and genetic effects).

Although the term "resilience" has not been clearly operationalized, it is generally used to describe children who (1) manage to avoid negative outcomes and/or to achieve positive outcomes despite being at significant risk for the development of psychopathology; (2) display sustained competence under stress; or (3) show recovery from trauma (Werner, 1995). Risk is usually defined in terms of child characteristics that are known to be associated with negative outcomes—for example, difficult temperament (Ingram & Price, 2001; Rothbart, Ahadi, & Evans, 2000)—and/or in terms of a child's exposure to extreme or disadvantaged environmental conditions (e.g., poverty or abuse). Individual children who are predisposed to develop psychopathology, and

who show a susceptibility to negative developmental outcomes under high-risk conditions, are referred to as "vulnerable." Genetic makeup and temperament are two factors that are presumed to contribute to susceptibility for children who are exposed to high-risk environments (Rutter, 1985; Seifer, 2000).

Further complicating such models are recent findings suggesting that certain genetic variants and temperament traits may serve not simply as markers of vulnerability to high-risk environments, but as markers of differential susceptibility to an array of positive and negative contexts (Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011). The notion of differential susceptibility to the environment means that some individual-difference factors will be linked to both especially negative *and* positive outcomes for children, depending on whether the early environment is harsh or one of nurturing support. In contrast, other children lacking such markers of plasticity (Ellis & Boyce, 2008) will tend to have intermediate outcomes regardless of the quality of the early environment. These two types of children (i.e., those highly responsive to their environments vs. those more resistant to environmental influence) have been compared to the delicate orchid and the hardy dandelion (Ellis & Boyce, 2008), with the so-called "dandelion" children exhibiting resilience in the context of early adversity.

Research on resilience has lacked a consistent vocabulary, conceptual framework, and methodological approach (Luthar et al., 2000; Masten, 2011; Rutter, 2000). It is particularly important to note that resilience is not defined as a universal, categorical, or fixed attribute of a child, but rather as a number of different types of dynamic processes that operate over time. Individual children may be resilient in relation to some specific stressors but not others, and resilience may vary over time and across contexts (Rutter, 2012). Models of resilience have increasingly begun to address the complex and dynamic relationships between the child and his or her environment, to incorporate the theoretical and empirical contributions of developmental psychology, and to acknowledge the multiple factors related to normal and deviant behavior (Rutter, 2006; Shiner & Masten, 2012).

One problem in research on resilience has been an absence of agreed-upon criteria for defining positive developmental outcomes (see Kaufman, Cook, Arny, Jones, & Pittinsky, 1994, for a review of the ways in which positive outcomes in studies of resilience have been operationalized). For example, there is currently debate as to whether the criteria for defining resilience and adaptation should be based on evidence from external criteria (e.g., academic performance), internal criteria (e.g., subjective well-being), or some combination of these (see Masten, 2001). Variations across studies in the source of information (e.g., parent or teacher); the type of assessment method (e.g., interview, questionnaire, observation); the adaptational criteria used; and the number and timing of assessments can easily influence the proportion of children who are designated as resilient or not in any particular investigation (Kaufman et al., 1994; Masten, 2001). In addition, there is also some confusion about, and circularity in, how the term "resilience" has been used, in that it has been used to refer both to an outcome and to the cause of an outcome. Furthermore, in instances in which resilience is used to refer to qualities of children that are putative markers of the capacity for positive adaptation despite adversity, it is important that such markers reflect capture more than the simple absence of vulnerability in order for them to have unique incremental validity for child outcomes beyond models of risk (see next section).

Several different models of resilience have also been proposed, the most common ones being a compensatory model, a challenge model (e.g., stress inoculation), and a protective-factors model (Garmezy, Masten, & Tellegen, 1984). Years of research suggest that resilience is not indicative of any rare or special qualities of a child per se (as implied by the term "the invulnerable child"), but rather is the result of the interplay of normal developmental processes such as brain development, cognition, personality development, caregiver–child relationships, regulation of emotion and behavior, and the motivation for learning (Masten, 2001). Some researchers have argued that resilience may be more ubiquitous than previously thought, and that this phenomenon is part of the "ordinary magic" and makeup of basic human adaptation (Masten, 2001; Sheldon & King, 2001). It is when these adaptational systems are impaired, usually through prolonged or repeated adversity, that the risk for childhood psychopathology increases.

Finally, the possibility that children may actually benefit from exposure to mild to moderate levels of stress has been proposed (e.g., Rutter, 2012; Taleb, 2012), but is not well understood from the standpoint of empirical research. In brief, the notion behind this hypothesis is that the experience of stress enables children to develop coping and other skills that permit them to

manage future stressors more successfully; if so, overly protective, hypervigilant parenting styles would have a negative impact on children, in part by preventing them from having such experiences. While this idea has common-sense appeal and complements exposure-based approaches to treating anxiety and other psychological problems, it has yet to accrue much in the way of research attention; it thus represents an important future direction in work on how stress influences child development.

Protective and Vulnerability Factors

Various protective and vulnerability factors have been found to influence children's reactions to potential risk factors or stressors (Kim-Cohen & Gold, 2009; Luthar, 2006). These include factors within the child, the family, and the community (Osofsky & Thompson, 2000; Werner & Smith, 1992). An example of a within-child risk factor would be cases in which individual differences in genetic risk moderate associations between adversity and negative outcomes (e.g., Brody et al., 2014). Common risk factors that have been found to have adverse effects on a child encompass both acute stressful situations and chronic adversity; they include such events as chronic poverty, poor caregiving, parental psychopathology, death of a parent, community disasters, homelessness, reduced social support, decreased financial resources, family breakup, parental marital/couple conflict, and perinatal stress (Brennan et al., 2008; Deater-Deckard & Dunn, 1999; Luecken & Lemery, 2004; Repetti, Taylor, & Seeman, 2002; Rutter, 1999; Tebes, Kaufman, Adnopoz, & Racusin, 2001).

Protective factors within a child that have been identified include an "easy" temperament (i.e., a child who is energetic, affectionate, cuddly, good-natured, and/or easy to deal with), which makes the child engaging to other people; early coping strategies that combine autonomy with help seeking when needed; high intelligence and scholastic competence; effective communication and problem-solving skills; positive self-esteem and emotions; high self-efficacy; genetic factors (i.e., Dodge & Sherrill, 2007); and the will to be or do something (Fredrickson, 2001; Gilgun, 1999). An example of possible protective factors within the child is seen in findings that high respiratory sinus arrhythmia in conjunction with high skin conductance—taken as indices of a child's ability to self-regulate via self-soothing, focused attention, and organized and goal-directed behavior—can buffer children from the increases in internalizing symptoms associated with exposure to parental marital conflict (El-Sheikh et al., 2013).

At a family level, protective factors that have been identified include the opportunity to establish a close relationship with at least one person who is attuned to the child's needs; positive parenting; availability of resources (e.g., child care); a talent or hobby that is valued by adults or peers; and family religious beliefs that provide stability and meaning during times of hardship or adversity (Werner & Smith, 1992). Protective factors in the community include extrafamilial relationships with caring neighbors, community elders, or peers; an effective school environment, with teachers who serve as positive role models and sources of support; and opening of opportunities at major life transitions (e.g., adult education, voluntary military service, church or community participation, a supportive friend or marital/relationship partner).

In summary, early patterns of adaptation influence later adjustment in complex and reciprocal ways. Adverse conditions, early adaptational struggles, and failure to meet developmental tasks do not inevitably lead to a fixed and unmalleable dysfunctional path (Rutter, 2007a). Rather, as noted earlier, many different factors can act to alter a child's developmental course for the better. Conversely, numerous events and circumstances may serve to alter this course for the worse.

The interrelated issues of developmental continuities–discontinuities; of developmental pathways; of risk, resilience, and antifragility; and of vulnerability and protective factors are far from being resolved or clearly understood. The multitude of interdependent and reciprocal influences, mechanisms, and processes involved in the etiology and course of child psychopathology clearly suggest a need for more complex theories (e.g., chaos theory, nonlinear dynamic models) (Granic, 2005; Glantz & Johnson, 1999), research designs, and data-analytic strategies (Rutter, 2007b; Singer & Willett, 2003).

Contextual Influences

Messick (1983) cogently argued that any consideration of child psychopathology must consider and account for three sets of contextual variables: (1) the child *as* context—the idea that unique child characteristics, predispositions, and traits influence the course of development; (2) the child *of* context—the notion that the child comes from a background of interrelated family, peer,

classroom, teacher, school, community, and cultural influences; and (3) the child *in* context—the understanding that the child is a dynamic and rapidly changing entity, and that descriptions taken at different points in time or in different situations may yield very different information.

Research has increasingly come to recognize the reciprocal transactions between the developing child and the multiple social and environmental contexts in which development and psychopathological symptoms occur (Deater-Deckard, 2001; Dirks, De Los Reyes, Briggs-Gowan, Cella, & Wakschlag, 2012). Understanding context requires a consideration of events that impinge directly on the child in a particular situation at a particular point in time; extrasituational events that affect the child indirectly (e.g., a parent's work-related stress); and temporally remote events that continue to affect the child through their representation in the child's current cognitive–affective database.

Certainly, relatively straightforward aspects of the physical context are known to affect child development (e.g., diet, lead; Chandramouli, Steer, Ellis, & Emond, 2009; Grantham-McGregor & Baker-Henningham, 2005). However, defining context has been, and continues to be, a matter of some complexity. The context of maltreatment provides an illustration of difficulties in definition. Maltreatment can be defined in terms of its type, timing, frequency, severity, and chronicity in the family (e.g., Manly, Kim, Rogosch, & Cicchetti, 2001). Each of these parameters and their interaction may contribute to child outcomes, but in different ways. For example, Manly, Cicchetti, and Barnett (1994) studied different types of maltreatment and found that outcomes generally did not differ for children who were categorized as neglected versus abused. However, a regression analysis indicated that neglect accounted for more of the variance in child problems than other types of abuse did. In this study, sexually abused children were also found to be more socially competent than children exposed to other forms of maltreatment. This may reflect a lack of chronicity associated with sexual abuse, or it may suggest that problems related to sexual abuse may not reveal themselves until later periods in a child's development, when issues concerning sexuality become more salient. Other studies have found that psychological maltreatment and emotional abuse account for most of the distortions in development attributed to maltreatment in general, and have the most negative consequences for a child (Crittenden, Claussen, & Sugarman, 1994).

The example of maltreatment illustrates how contexts for development encompass heterogeneous sets of circumstances, and how child outcomes may vary as a function of (1) the configuration of these circumstances over time, (2) when and where outcomes are assessed, and (3) the specific aspects of development that are affected. More precise definitions are needed if the impact of maltreatment—or, for that matter, any contextual event (e.g., parent disciplinary styles, family support, intellectual stimulation, nutrition)—is to be understood.

Even for those forms of child psychopathology for which there are strong neurobiological influences, the expression of the disorder is likely to interact with contextual demands. For example, Iaboni, Douglas, and Baker (1995) found that although the overall pattern of responding shown by children with ADHD was indicative of a generalized inhibitory deficit, the self-regulatory problems of these children became more evident with continuing task demands for inhibition and/or deployment of effort. Likewise, tasks having high interest value or high external incentives may moderate these children's typically deficient performance on less interesting or low-incentive tasks (Carlson & Tamm, 2000; Slusarek, Velling, Bunk, & Eggers, 2001).

Child psychopathology research has increasingly focused on the role of the family system, the complex relationships within families, and the reciprocal influences among various family subsystems (Fiese, Wilder, & Bickham, 2000). There is a need to consider not only the processes occurring within disturbed families, but the common and unique ways in which these processes affect both individual family members and subsystems. Within the family, the roles of the mother–child and marital/couple subsystems have received the most research attention to date, with less attention given to the roles of siblings (Hetherington, Reiss, & Plomin, 1994) and fathers (Phares, Rojas, Thurston, & Hankinson, 2010). For the most part, research into family processes and child psychopathology has not kept pace with family theory and practice, and there is a need for the development of sophisticated methodologies and valid measures that will capture the complex relationships hypothesized to be operative in disturbed and normal family systems (Bray, 1995; Bray, Maxwell, & Cole, 1995). This task is complicated by a lack of consensus concerning how healthy family functioning or family dysfunction should be defined; what specific family processes are important to assess (Mash & Johnston, 1995); or the extent to which such measures of fam-

ily environment reflect true environmental effect or shared genetic influences between parent and child (Plomin, 1995).

DEFINING CHILD PSYCHOPATHOLOGY

There has been, and continues to be, a lack of consensus concerning how psychopathology in children should be defined (Angold & Costello, 2009; Rutter, 2011). Despite ongoing debate, for pragmatic purposes, researchers and clinicians typically define child psychopathology using standardized diagnostic systems such as the most recent revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association [APA], 2013a) and the *International Classification of Diseases*, 10th revision (ICD-10; WHO, 2010). The diagnostic criteria utilized in DSM-5 are the ones most commonly used in North America, and these are presented for the individual disorders described in each subsequent chapter of this volume. However, the increased use and acceptance of DSM-5 and its predecessors should not be taken as an indication of widespread agreement regarding the fundamental nature of what constitutes psychopathology in children or the specific criteria used to define it (cf. Coghill & Sonuga-Barke, 2012; Hudziak et al., 2007; Rutter, 2011). In many ways, the acceptance and use of DSM-5 seems to reflect a degree of resignation on the part of many researchers and clinicians concerning the prospects for developing a widely agreed-upon alternative approach. Nevertheless, alternative approaches are being advanced that apply current research findings toward the development of classification frameworks for psychopathology (Insel et al., 2010; Sanislow et al., 2010), as discussed later in this chapter.

Several fundamental questions have characterized most discussions concerning how child psychopathology should be defined:

1. Should child psychopathology be viewed as a disorder that occurs within the individual child (e.g., disorder of the brain, psychological disturbance), as a relational disturbance, as a reaction to environmental circumstances, or (as is likely) some combination of all these?

2. Does child psychopathology constitute a condition qualitatively different from normality (aberration), an extreme point on a continuous trait, a delay in the rate at which a normal trait would typically emerge, or some combination of the three? How are "subthreshold" problems to be handled?

3. Can homogeneous disorders be identified? Or is child psychopathology best defined as a configuration of co-occurring disorders or as a profile of traits and characteristics?

4. Can child psychopathology be defined as a static entity at a particular point in time, or do the realities of development necessitate that it be defined as a dynamic and ongoing process that expresses itself in different ways over time and across contexts?

5. Is child psychopathology best defined in terms of its current expression, or do definitions also need to incorporate nonpathological conditions that may constitute risk factors for later problems? This question is especially relevant when considering disorder and risk for disorder in infants and toddlers (see Lyons-Ruth, Zeanah, Benoit, Madigan, & Mills-Koonce, Chapter 15, this volume).

There are currently no definitive answers to these questions. More often, the way in which they are answered reflects theoretical or disciplinary preferences and utility, such as specific purposes and goals (e.g., defining samples for research studies, or determining program or insurance eligibility).

Psychopathology as Adaptational Difficulty

As we have noted earlier, a common theme in defining child psychopathology has been that of adaptational difficulty or failure (Garber, 1984; Mash, 1998). Sroufe and Rutter (1984) note that regardless of whether "particular patterns of early adaptation are to a greater or lesser extent influenced by inherent dispositions or by early experience, they are nonetheless patterns of adaptation" (p. 23). Developmental competence is reflected in a child's ability to use internal and external resources to achieve a successful adaptation (Masten, Burt, & Coatsworth, 2006; Waters & Sroufe, 1983), and problems occur when the child fails to adapt successfully. Even with wide variations in terminology and proposed explanatory mechanisms across theories, there is general agreement that maladaptation represents a pause, a regression, or a deviation in development (Garber, 1984; Simeonsson & Rosenthal, 1992).

In conceptualizing and defining psychopathology as adaptational difficulty, it is also essential to conceptualize and identify the specific developmental tasks and challenges that are important for children at various ages and periods of development, and the many contextual variables that derive from and surround the child (Garber, 1984; Luthar, Burack, Cicchetti, & Weisz, 1997; Mash, 1998). In this regard, the study of psychopathology in children and the study of development and context are for all intents and purposes inseparable (Cicchetti & Aber, 1998).

In determining whether a given behavior should be considered to be deviant in relation to stage-salient developmental issues, Garber (1984) stresses the need to understand several important parameters. The first, "intensity," refers to the magnitude of behavior as excessive or deficient. The second, "frequency," refers to the severity of the problem behavior, or how often it does or does not occur. Third, the "duration" of behavior must be considered. Some difficulties are transient and spontaneously remit, whereas others persist over time. To these parameters, we would add a qualitative parameter reflecting how grossly atypical the behavior may be (e.g., some of the complex compulsions seen in Tourette's disorder), such that even low-intensity, low-frequency, and short-duration behavior may be so bizarre as to constitute "psychopathology." It is crucial that the intensity, frequency, duration, and atypicality of the child's behavior be appraised with respect to what is considered normative for a given age (e.g., the developmental appropriateness of a behavior). The final parameter of deviance concerns the "number of different symptoms" and their "configuration." Each of these parameters is central to research and theory, and to one's specific definition of adaptational failure, regression, stagnation, or deviation.

Social Judgment

The diagnosis of psychopathology in children is almost always a reflection of both the characteristics and behavior of the child *and* of significant adults and professionals (Lewis, 2000). Research findings utilizing behavior problem checklists and interviews indicate that there can be considerable disagreement across informants (e.g., parents, teachers, professionals) concerning problem behaviors in children (Achenbach, McConaughy, & Howell, 1987; Feiring & Lewis, 1996; Youngstrom, 2013). Mothers typically report more problems than do fathers (e.g., Achenbach et al., 1991), and across a range of domains, teachers identify more problems than other informants do in assessing the same domains. For example, in a study with maltreated children, only 21% were classified as resilient by teachers, whereas 64% were so classified based on reports from other sources (Kaufman et al., 1994).

Issues regarding disagreement–agreement among informants are complicated by the fact that the amount of agreement will vary with the age and sex of the child (Offord, Boyle, & Racine, 1989), the nature of the problem being reported on (e.g., internalizing vs. externalizing; De Los Reyes & Kazdin, 2005), the method used to gather information (e.g., interview vs. questionnaire), and the informants being compared. For example, Tarullo, Richardson, Radke-Yarrow, and Martinez (1995) found that both mother–child and father–child agreement was higher for preadolescent than for adolescent children; in a meta-analysis, Duhig, Renk, Epstein, and Phares (2000) reported higher mother–father agreement for externalizing than for internalizing problems. Disagreements among informants create methodological difficulties in interpreting epidemiological data when such data are obtained from different sources, and also in how specific diagnoses are arrived at in research and practice. For most research studies, the practice tends to be to consider a symptom present if any informant endorses it as such (e.g., Costello, Mustillo, et al., 2003).

Also of importance is how disagreements among informants are interpreted (De Los Reyes, 2011). For example, disagreements may be viewed as (1) reflections of bias or error on the part of one informant; (2) evidence for the variability of children's behavior across the situations in which they are observed by others; (3) lack of access to certain types of behavior (i.e., private events) on the part of one informant; (4) denial of the problem; or (5) active distortion of information in the service of some other goal (e.g., defensive exclusion, treatment eligibility).

Parental psychopathology may "color" descriptions of child problems—as may occur when abusive or depressed mothers provide negative or exaggerated descriptions of their children (Gotlib & Hammen, 1992; Mash et al., 1983; Richters, 1992; Youngstrom, Izard, & Ackerman, 1999), or when dismissive/avoidant adult informants deny the presence of emotional problems at the same time that professionals observe a high level of symptoms (Dozier & Lee, 1995). These latter types of problems in reporting may be especially likely, given

the frequent lack of correspondence between the expression and the experience of distress for many child and adult disturbances. Hypothesized relationships between parental psychopathology and reports of exaggerated child symptoms have received mixed support. For example, some studies have failed to find evidence for distorted reports by depressed mothers (Tarullo et al., 1995). However, recent work (Durbin & Wilson, 2012) examining maternal ratings of child behavior also coded by objective raters found that mothers' lifetime psychiatric diagnoses and personality traits were associated with their reports of child emotional behavior, and that for some emotions, mothers' mental health and dispositional variables were more strongly related to their reports of their children's emotions than were objective indices of the children's observable emotional behavior. Related work (Hayden, Durbin, Klein, & Olino, 2010) indicates that maternal characteristics, such as mothers' own personality traits, influence the extent to which they successfully encode and/or report on analogous child behaviors. Intriguingly, the extent to which informant discrepancies are present regarding child behavior may predict poor child outcomes, above and beyond individual informants' reports of children (De Los Reyes, 2011). Thus, while it is well known that informant discrepancies exist, the meaning of these discrepancies and their implications for child outcomes requires further study.

APPROACHES TO CONCEPTUALIZING CHILD PSYCHOPATHOLOGY

The types of problems for which children are referred for treatment are reflected in the different approaches that have been used to conceptualize and classify these problems. Among the more common of these approaches are the following:

1. General and specific behavior problem checklists, which enumerate individual child symptoms—for example, the Child Behavior Checklist (Achenbach & Rescorla, 2001) and the Children's Depression Inventory 2 (Kovacs, 2010).
2. Dimensional approaches, which focus on symptom clusters or syndromes, derived from behavior problem checklists—for example, the Child Behavior Checklist and Profile (Achenbach, 1993; Achenbach & Rescorla, 2001).
3. Categorical approaches, which use predetermined diagnostic criteria to define the presence or absence of particular disorders—for example, DSM-5 (APA, 2013a) and ICD-10 (WHO, 2010).[5]
4. A multiple-pathway, developmental approach, which emphasizes developmental antecedents and competencies both within the child and the environment that contribute to (mal)adjustment and (mal) adaptation (Sroufe, 1997).

Issues related to the use of these different classification approaches are discussed in a later section of this chapter. What follows is a brief overview of the types of problem behaviors, dimensions, and disorders that occur during childhood and that are the topics of this volume's other chapters.

Individual Symptoms

For the most part, individual behavioral and emotional problems (i.e., symptoms) that characterize most forms of child psychopathology occur in almost all children at one time or another during their development (e.g., Achenbach & Edelbrock, 1981; Achenbach et al., 1991; MacFarlane et al., 1954). When taken in isolation, specific symptoms have generally shown little correspondence to a child's overall current adjustment or to later outcomes. This is the case even for many symptoms hypothesized to be significant indicators of psychopathology in children in earlier decades—for example, thumbsucking after 4 years of age (Friman, Larzelere, & Finney, 1994). Usually the age-appropriateness, clustering, and patterning of symptoms are what serve to define child psychopathology, rather than the presence of individual symptoms.

Many of the individual behavior problems displayed by children referred for treatment are similar to those that occur in less extreme forms in the general population or in children of younger ages. For example, Achenbach and colleagues (1991) found that although referred children scored higher than nonreferred children on 209 of 216 parent-rated problems, only 9 of the 209 items showed effects related to clinical status that were considered to be large (accounting for more than 13.8% of the variance), according to criteria specified by Cohen (1988). Examples of parent-reported individual symptoms that were more common in referred than in nonreferred children and that accounted for 10% or more of the variance in clinical status included "sad or

depressed," "uncooperative," "nervous," "high-strung, or tense," "feels he/she can't succeed," "feels worthless or inferior," "disobedient at school," "easily distracted," "lies," "fails to finish things he/she starts," "defiant," and "doesn't get along with other kids" (Achenbach et al., 1991). As can be seen, even the problems that best discriminated between referred and nonreferred children are relatively common behaviors that occur to some extent in all children; they are not particularly strange or unusual behaviors. In addition, most *individual* problem behaviors (approximately 90% of those on behavior problem checklists) do not, by themselves, discriminate between groups of clinic-referred and nonreferred children. Nondiscriminating items include some problems for children in both groups that are relatively common (e.g., "brags," "screams") and others that occur less frequently (e.g., "sets fires," "bowel movements outside the toilet").

Dimensions of Child Psychopathology

A second approach to describing child psychopathology identifies symptom clusters or "syndromes" derived through the use of multivariate statistical procedures, such as factor analysis or cluster analysis (e.g., Achenbach, 1993, 1997; McDermott, 1993; McDermott & Weiss, 1995). Research has identified two broad dimensions of child psychopathology—one reflecting "externalizing" or "undercontrolled" problems, and the other reflecting "internalizing" or "overcontrolled" problems (Reynolds, 1992). The externalizing dimension encompasses behaviors often thought of as directed at others, whereas the internalizing dimension describes feelings or states that are commonly viewed as "inner-directed." The presense of these two dimensions may account for the pervasive comorbidity found between internalizing (e.g., depression and anxiety) and externalizing (e.g., oppositional and conduct problems) disorders; moreover, extensions of this research applied to adults suggest that a similar structure may characterize adult psychopathology (Krueger & Markon, 2006; although see Kotov et al., 2011), thus supporting the lifespan continuity of this dimensional structure. Within the two broad dimensions of externalizing and internalizing disorders, there may be further subdimensions or syndromes, including anxious/depressed (e.g., "crying," "fearful of multiple situations"), withdrawn/depressed (e.g., "enjoys little," "withdrawn"), somatic complaints (e.g., "feels dizzy," "tired"), social problems (e.g., "lonely," "gets teased"), thought problems (e.g., "hears or sees things"), attention problems (e.g., "problems sitting still or attending"), rule-breaking behavior (e.g., "steals," "swears"), and aggressive behavior (e.g., "argumentative," "physically aggressive") (Achenbach & Rescorla, 2001).

Categories of Child Psychopathology

The DSM-5 diagnostic system (APA, 2013a) provides comprehensive coverage of the general types of symptom clusters displayed by children characterized as having mental disorders. To illustrate, DSM-5 categories that apply to children are listed in Tables 1.1–1.3. These tables are not intended to be exhaustive of all DSM-5 diagnoses that may apply to children. Rather, they are intended to provide an overview of the range and variety of disorders that typically occur during childhood. Specific DSM-5 disorders and their subtypes are discussed in detail in the subsequent chapters of this volume.

Table 1.1 lists the DSM-5 categories for neurodevelopmental disorders, including intellectual disability, communication disorders (e.g., language disorder), autism spectrum disorder, ADHD, specific learning disorder, and motor disorders. Most of these disorders are early-emerging, often co-occurring conditions characterized by deficits and delays in attaining developmental milestones, and are associated with a range of impairments in multiple domains of functioning (e.g., social, academic). An array of specifiers, such as age of onset and severity, can be applied to provide further detail to the clinical description of individual patients and to aid prediction of the disorder's course. Whether the disorder is accompanied by a medical or genetic condition or an environmental factor with potential etiological significance (e.g., fetal alcohol exposure) can also be noted as part of the diagnosis.

Table 1.2 is a noncomprehensive list of DSM-5 categories for other disorders that can be diagnosed in children or adolescents (e.g., schizophrenia, depressive disorders, bipolar and related disorders, anxiety disorders). It is noteworthy that, unlike its immediate predecessors, the DSM-5 does not contain a separate section on disorders of infancy and childhood; instead, disorders previously located in this section in DSM-IV are now found in the section for neurodevelopmental disorders (e.g., ADHD) or are integrated in other sections throughout the manual (e.g., separation anxiety

TABLE 1.1. DSM-5 Categories for Neurodevelopmental Disorders

Intellectual disabilities
Intellectual disability (intellectual developmental disorder)
Global developmental delay
Unspecified intellectual disability
Communication disorders
Language disorder
Speech sound disorder
Childhood-onset fluency disorder (stuttering)
Social (pragmatic) communication disorder
Unspecified communication disorder
Autism spectrum disorder
Autism spectrum disorder
Attention-deficit/hyperactivity disorder
Attention-deficit/hyperactivity disorder
Other specified attention-deficit/hyperactivity disorder
Unspecified attention-deficit/hyperactivity disorder
Specific learning disorder
Specific learning disorder
Motor disorders
Developmental coordination disorder
Stereotypic movement disorder
Tourette's disorder
Persistent (chronic) motor or vocal tic disorder
Provisional tic disorder
Other specified tic disorder
Unspecified tic disorder
Other neurodevelopmental disorders
Other specified neurodevelopmental disorder
Unspecified neurodevelopmental disorder

TABLE 1.2. Select DSM-5 Categories for Other Disorders Diagnosed in Infancy, Childhood, or Adolescence

Schizophrenia spectrum and other psychotic disorders
Schizotypal personality disorder; schizophrenia; schizoaffective disorder; schizophreniform disorder; delusional disorder; brief psychotic disorder
Bipolar and related disorders
Bipolar I disorder; bipolar II disorder; cyclothymic disorder
Depressive disorders
Disruptive mood dysregulation disorder; major depressive disorder, single episode or recurrent episodes; persistent depressive disorder (dysthymia)
Anxiety disorders
Separation anxiety disorder; selective mutism; specific phobia; social anxiety disorder (social phobia); panic disorder; agoraphobia
Obsessive–compulsive and related disorders
Obsessive–compulsive disorder; body dysmorphic disorder; hoarding disorder; trichotillomania (hair-pulling disorder); excoriation (skin-picking) disorder
Trauma- and stressor-related disorders
Reactive attachment disorder; disinhibited social engagement disorder; posttraumatic stress disorder; acute stress disorder; adjustment disorders
Feeding and eating disorders
Pica; Rumination disorder; avoidant/restrictive food intake disorder; anorexia nervosa; bulimia nervosa; binge-eating disorder
Elimination disorders
Enuresis; encopresis
Disruptive, impulse-control, and conduct disorders
Oppositional defiant disorder; intermittent explosive disorder; conduct disorder; antisocial personality disorder; pyromania; kleptomania
Substance-related and addictive disorders
Substance use disorders; substance-induced disorders

disorder). This change was made with the goal of emphasizing a lifespan approach to conceptualizing mental disorders, and in recognition of the fact that many disorders can and do manifest themselves across the lifespan (APA, 2013b). Although it is true that boundaries drawn between disorders of childhood and other age groups are arbitrary, and potentially hamper tests of psychopathology continuity over time, the long-term implications of this significant change to DSM organization are unclear. The addition of a specific section dedicated to disorders of childhood to DSM-III is widely regarded as having played a critical role in increasing research interest in childhood disorders; whether removing this distinction will result in a decrease in the level of attention being paid to disorders of children remains to be seen.

Finally, Table 1.3 is a noncomprehensive list of DSM-5 categories for other conditions that are not defined as mental disorders, but may be a focus of clinical attention. We have focused on those with the greatest relevance for childhood or adolescence, in that they emphasize relational problems, maltreatment, and academic and adjustment difficulties.

TABLE 1.3. DSM-5 Categories for Other Conditions That May Be a Focus of Clinical Attention

Relational problems
Problems related to family upbringing (e.g., parent–child relationship problem; child affected by parental relationship distress)
Other problems related to primary support group (e.g., disruption of family by separation or divorce; uncomplicated bereavement)
Abuse and neglect
Child maltreatment and neglect problems (e.g., confirmed and suspected physical and sexual abuse; confirmed and suspected neglect; encounters for mental health services for these problems)
Educational and occupational problems
Educational problems (e.g., academic problems)
Housing and economic problems
Housing problems (e.g., homelessness; inadequate housing)
Economic problems (e.g., lack of adequate food or safe drinking water; extreme poverty; low income)

APPROACHES TO THE CLASSIFICATION AND DIAGNOSIS OF CHILD PSYCHOPATHOLOGY

There is general agreement in medicine, psychiatry, and psychology regarding the need for a system of classifying childhood disorders. However, major areas of contention have arisen around such issues as which disorders should be included in the system, what the optimal strategies are for organizing and grouping disorders, and which specific criteria should be used to define a particular disorder (Achenbach, 1985; Achenbach & Edelbrock, 1989; Mash & Barkley, 2007; Sonuga-Barke, 1998).

The two most common approaches to the diagnosis and classification of child psychopathology involve the use of (1) "categorical" classification systems that are based primarily on informed clinical consensus, an approach that has dominated and continues to dominate the field (APA, 1994, 2000, 2013a); and (2) empirically based "dimensional" classification schemes derived through the use of multivariate statistical techniques (Achenbach, 1993, 1997; Achenbach & Rescorla, 2001). In addition, alternative and/or derivative approaches to classification have been proposed to address perceived deficiencies associated with the use of categorical and dimensional approaches. These have included developmentally based measures (Garber, 1984; Mohr & Regan-Kubinski, 1999; Sroufe, 1997), laboratory and performance-based measures (Frick, 2000), prototype classification (Cantor et al., 1980; Shaffner, 2012), and behavioral classification/functional analysis based on behavioral excesses, deficits, and faulty stimulus control (Mash & Hunsley, 1990; Ringdahl & Falcomata, 2009). Although each of these alternative approaches has something to offer to the classification of childhood disorders, they are generally underdeveloped and unstandardized, and have not been widely accepted or used in either research or practice.

In addition to these alternatives, the limitations of diagnostic systems derived from expert consensus (e.g., DSM-5) have led to both a call for greater emphasis on the underlying neurobiological substrates of psychopathology in classification, and a response, by virtue of the development of the Research Domain Criteria (RDoC; Insel et al., 2010; Sanislow et al., 2010). The RDoC initiative, which was spearheaded by the National Institute of Mental Health, aims to generate research on the biological substrates of psychopathology, with

the goal of developing future classification schemes that map more clearly onto the underlying pathophysiology of disorder. Multiple workshops were held in 2010–2012 with the goal of defining various domains of functioning (e.g., cognitive systems, arousal/regulatory systems), which were further broken down into constructs (e.g., attention, circadian rhythms) that have units of analysis with genetic, molecular, neural, and behavioral levels (Morris & Cuthbert, 2012), although the primary focus of RDoC is on neural circuitry (Insel et al., 2010). It is already known that many if not all of these levels of analysis will cut across disorders as they are traditionally defined, which can be taken as evidence for the failure of current diagnostic systems to "carve nature at its joints" and for the need for the RDoC framework.

One long-term goal of the RDoC initiative is that genetic sequencing, brain imaging, and other laboratory-based approaches will supplant diagnostic systems based on clinical consensus, play a central role in clinical assessments, and directly inform treatment (Insel, 2013; Insel et al., 2010). This is clearly a highly ambitious goal, given the currently limited ability of genetic and neuroimaging findings to predict treatment response or other important clinical outcomes; at present, most constructs with the capacity to predict clinical outcomes (e.g., age of onset, negative life events) would be considered "psychological" or "behavioral" rather than biological. Furthermore, embedded within the RDoC initiative is the notion that mental disorders are disorders of the brain, and can be best understood, and ultimately treated, through the application of clinical neuroscience methodologies and genomics. This viewpoint could be considered reductionistic; at the least, it is an empirical stance that may or may not ultimately be supported by data. Thus, while the core premise behind RDoC (i.e., that contemporary diagnostic systems do not map closely onto etiology, although it would be desirable for them to do so) is not especially controversial, the perceived preeminence of biological approaches to disorder may be to some in the field.

To date, no single classification scheme for childhood disorders has established adequate validity (Cantwell, 1996; Mash & Barkley, 2007; Rutter & Uher, 2012). Many researchers and clinicians have expressed and continue to express concerns that current diagnostic and classification systems (1) underrepresent disorders of infancy and childhood; (2) are inadequate in representing the interrelationships and overlap that exist among many childhood disorders; (3) are not sufficiently sensitive to the developmental, contextual, and relational parameters that are known to characterize most forms of psychopathology in children; and (4) are heterogeneous with respect to etiology (Jensen & Hoagwood, 1997; Kagan, 1997; Rice, 2010).

Categorical Approaches

Categorical approaches to the classification of childhood disorders have included systems developed by the Group for the Advancement of Psychiatry (1974), the WHO (2010), the APA (2013a), and the Zero to Three/National Center for Clinical Infant Programs (2005a). Although a detailed review of all these systems is beyond the scope of this chapter, a brief history of the APA's development of the DSM approach is presented to illustrate the issues associated with categorical approaches, the growing concern for more reliable classification schemes for childhood disorders, and the evolving conceptualizations of childhood disorders over the past 60 years. Discussion of the DSM approach in relation to specific child and adolescent disorders appears in the chapters that follow. Also, the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood-Revised*, or *Diagnostic Classification: 0–3R* (DC:0–3R; Zero to Three/National Center for Clinical Infant Programs, 2005a), is described to illustrate a categorical approach that attempts to integrate developmental and contextual information into the diagnosis of infants' and young children's problems.

Development of the DSM Approach

One of the first efforts to collect data on mental illness was in the U.S. census of 1840, which recorded the frequency of a single category of "idiocy/insanity." Forty years later, seven categories of mental illness were identified: dementia, dipsomania, epilepsy, mania, melancholia, monomania, and paresis (APA, 1994). Much later (in the 1940s), the WHO classification system emerged with the manuals of the ICD, whose sixth revision included, for the first time, a section for mental disorders (APA, 1994; Cantwell, 1996).

In response to perceived inadequacies of the ICD system for classifying mental disorders, the APA's Committee on Nomenclature and Statistics developed DSM-I in 1952 (APA, 1952). There were three major categories of dysfunction in DSM-I—"organic brain syndromes," "functional disorder," and "mental defi-

ciency" (Kessler, 1971)—under which were subsumed 106 categories. The term "reaction" was used throughout the text, which reflected Adolf Meyer's psychobiological view that mental illness involves reactions of the personality to psychological, social, and biological factors (APA, 1987). Children were largely neglected in the early versions of DSM (Cass & Thomas, 1979; Silk et al., 2000). In fact, DSM-I included only one child category of "adjustment reactions of childhood and of adolescence," which was included under the heading of "transient situational disorders."

As reflected in the use of the term "reaction," psychoanalytic theory had a substantial influence on the classification of both child and adult psychopathology (Clementz & Iacono, 1993). In part, this was due to the fact that the first classification system to focus on childhood psychopathology was developed by Anna Freud in 1965 (see Cantwell, 1996). Although the term "reaction" was eliminated from DSM-II (APA, 1968), a separate section was reserved for classifying neuroses, and diagnoses could be based on either an assessment of the client's presenting symptomatology or inferences about his or her unconscious processes (Clementz & Iacono, 1993). Once again, apart from conditions subsumed under the adult categories, DSM-II gave little recognition to childhood difficulties except for mental retardation and schizophrenia—childhood type (Cass & Thomas, 1979).

As a formal taxonomy, DSM-III (APA, 1980) represented a substantial departure from, and advance over, earlier editions of the DSM. The first and second editions contained only narrative descriptions of symptoms, and clinicians had to draw on their own definitions for making a diagnosis (APA, 1980); thus interrater reliability of psychiatric diagnoses was quite poor. DSM-III, in which explicit inclusion, exclusion, and duration criteria for each disorder were included, represented a landmark shift of the field aimed at achieving greater diagnostic reliability (Achenbach, 1985; APA, 1980). Moreover, unsubstantiated etiological inferences that were heavily embedded in psychoanalytic theory were dropped, more child categories were included, and a greater emphasis was placed on empirical data (Achenbach, 1985). These changes reflected the beginnings of a conceptual shift in both diagnostic systems and etiological models away from an isolated focus of psychopathology as existing within the child alone, and toward an increased emphasis on his or her surrounding context. DSM-III was revised in 1987 (DSM-III-R) to help clarify the inconsistencies and ambiguities that arose in its use. For example, empirical data at that time did not support the category of attention deficit disorder *without* hyperactivity as a unique symptom cluster (Routh, 1990), and this category was removed from DSM-III-R. DSM-III-R was also developed to be polythetic, in that a child could be diagnosed with a certain subset of symptoms without having to meet all criteria. This was an important change, especially in light of the heterogeneity and rapidly changing nature of most childhood disorders (Mash & Barkley, 2007). Relative to its predecessors, far greater emphasis was also placed on empirical findings in the development of DSM-IV, particularly for the child diagnostic categories.

In order to bridge the planned 12-year span between DSM-IV and DSM-5, a revision (DSM-IV-TR) of DSM-IV was published in 2000 (APA, 2000). DSM-IV-TR was limited to text revisions (e.g., associated features and disorders, prevalence) and was designed mainly to correct any factual errors in DSM-IV, make sure that information was still current, and incorporate new information since the time the original DSM-IV literature reviews were completed in 1992. In 2013, after a considerable delay, DSM-5 was released.

Although contemporary versions of DSM have included numerous improvements over previous DSMs—with their greater emphasis on empirical research, and more explicit diagnostic criteria sets and algorithms—criticisms have also been raised (e.g., Hyman, 2010; Rutter, 2011; Uher & Rutter, 2012). First, although DSM-5 incorporates greater dimensional representation of disorders than its predecessors, it still relies largely on a categorical scheme that may not always optimally serve children's needs. For example, it may be necessary for a child to meet specific diagnostic criteria for specific learning disorder in order to qualify for a special education class. However, if the child's problems are subclinical, or the child's problems relate to more than one DSM category, then he or she may be denied services (Achenbach, 2000). Useful approaches to the goal of incorporating the strengths of dimensional operationalizations of disorder (e.g., increased information) with those of categorical approaches (e.g., ease of communication) have been proposed (e.g., Kamphuis & Noordhof, 2009) and should be applied more frequently in the field.

Another problem with DSM-5 relates to the wording and the lack of empirical adequacy for certain criterion sets. For example, the words "often" in the criteria for ADHD and conduct disorder, and "persistent" and "excessive" in the criteria for separation anxiety disorder,

are not clearly defined. This ambiguity poses a particular problem when one considers that the primary sources of assessment information are often a child's parents, whose perception and understanding of these terms may be idiosyncratic or inaccurate. This ambiguity and other factors may contribute to the unreliability or unsuitability of the DSM for diagnosing certain childhood disorders (e.g., Nicholls, Chater, & Lask, 2000).

A further difficulty with DSM-5 diagnostic criteria is the lack of emphasis on the situational or contextual factors surrounding and contributing to various disorders. This is a reflection of the fact that DSM-5 continues to view mental disorder as individual psychopathology or risk for psychopathology, rather than in terms of problems in psychosocial adjustment. One problem with respect to the atheoretical nature of DSM is that it has perhaps mistakenly fostered the assumption that a description of symptoms is sufficient for diagnosis, without taking into account natural history, psychosocial correlates, biological factors, or response to treatment (Cantwell, 1996). However, the consideration in DSM-5 of such factors as culture, age, and gender associated with the expression of each disorder is laudable, as is the increased recognition of the importance of family problems and extrafamilial relational difficulties.

Other concerns exist, including the extent to which comorbidity is an artifact of the DSM's polythetic criteria (Angold, Costello, & Erkanli, 1999; Nottelmann & Jensen, 1995), or whether the pendulum has swung too far from not identifying psychopathological conditions in children to overly liberal diagnostic practices that label relatively healthy children as disordered (Silk et al., 2000). It is also the case that ongoing changes in diagnostic criteria based on new findings and other considerations (e.g., eligibility for services) are likely to influence prevalence estimates for many childhood disorders. For example, current estimates of the prevalence of autism spectrum disorder (e.g., Kogan et al., 2009) are substantially higher than even fairly recent, previous ones (e.g., Fombonne, 1999; Tanguay, 2000); this increase is primarily due to a broadening of the criteria used to diagnose autism spectrum disorder, as well as increased recognition of milder forms of the disorder and changes in case-finding approaches (Costello, Foley, & Angold, 2006).

Development of the DC:0–3R System

In addition to the limitations noted above, DSM-5 does not provide in-depth coverage of the mental health and developmental problems of infants and young children, for whom such problems are frequently nested within the context of the family. To address this perceived deficiency, DC:0–3 and DC:0–3R, the current version, were developed by the Diagnostic Classification Task Force of the Zero to Three/National Center for Clinical Infant Programs (1994, 2005a). The revised version, developed after a decade's use of the original, primarily differs from the DC:0–3 in terms of its increased use of specific criteria to operationalize disorders, and thus increase interrater reliability (Zero to Three/National Center for Clinical Infant Programs, 2005b; Postert, Averbeck-Holocher, Beyer, Müller, & Furniss, 2009), although few data are available to speak to whether this aim was achieved. The DC:0–3R is intended to provide a comprehensive system for classifying problems during the first 3–4 years of life (Zero to Three/National Center for Clinical Infant Programs, 2005b). Unlike DSM-5, DC:0–3R is based on the explicit premise that diagnosis must be guided by the principle that infants and young children are active participants in relationships within their families. Hence descriptions of infant–caregiver interaction patterns, and of the links between these interaction patterns and adaptive and maladaptive patterns of infant and child development, constitute an essential part of the diagnostic process.

In explicitly recognizing the significance of relational functioning, DC:0–3R includes a relationship classification as a separate axis (Axis II) in its multiaxial approach (Axis I, clinical disorders; Axis III, medical and developmental disorders and conditions; Axis IV, psychosocial stressors; Axis V, emotional and social functioning). The formal classification of relationships is based on observations of parent–child interaction and information about the parent's and child's subjective experience. In classifying DC:0–3R Axis II, evidence for parental over-/underinvolvement, anxiety/tension, and anger/hostility are rated, and the clinician assesses the intensity, frequency, and duration of difficulties in the relationship, classifying these as either perturbation, disturbance, or disorder. Axis V of DC:0–3R, emotional and social functioning, includes the ways in which infants or young children organize their affective, interactive, and communicative experiences. Axis V assessment is based in large part on direct observations of parent–child interaction. The various levels include social processes such as mutual attention, mutual engagement or joint emotional involvement, reciprocal interaction, and affective/ symbolic communication. Problems may reflect constrictions in range of affect

within levels or under stress, or failure to reach expected levels of emotional development.

DC:0–3R differs significantly from other classification systems in recognizing the significance of early relational difficulties and the need to integrate diagnostic and relational approaches in classifying child psychopathology. In addition, the dimensions and specific processes that are used for classification (e.g., negative affect, unresponsivity, uninvolvement, lack of mutual engagement, lack of reciprocity in interaction) include those that have been identified as important in many developmental and clinical research studies on early relationships, and the system is decidedly more sensitive to developmental and contextual parameters than DSM-5. However, although promising, DC:0–3R is still relatively untested and suffers from many of the same criticisms that have been noted for DSM-5 (Eppright, Bradley, & Sanfacon, 1998). Nevertheless, the scheme provides a rich descriptive base for exploring the ways in which psychopathology is expressed during the first few years of life, and it calls attention to the need to examine potential continuities between early problems and later individual and/or family disorders (Postert et al., 2009).

Dimensional Approaches

Dimensional approaches to classification assume that a number of relatively independent dimensions or traits of behavior exist, and that all children possess these to varying degrees. These traits or dimensions are typically derived through the use of multivariate statistical methods, such as factor analysis or cluster analysis (Achenbach, 1993). Empirically derived schemes are more objective, usually more reliable, and more informative than clinically derived classification systems. However, several problems are also associated with their use, including their complexity, as well as the dependency of the derived dimensions on sampling, method, and informant characteristics, and on the age and sex of the children (Mash & Barkley, 2007). As a result, there can be difficulties in integrating information obtained from different methods, from different informants, over time, or across situations. Dimensional approaches have also shown a lack of sensitivity to contextual influences, although there have been efforts to develop dimensional classification schemes based on item pools that include situational content (e.g., McDermott, 1993). Moreover, in many applied contexts, "categorical" decisions regarding treatment must be made, such whether to engage in treatment. Thus most dimensional measures typically provide thresholds to indicate points at which symptoms are clinically significant to facilitate decisions regarding whether treatment should be implemented, effectively reducing such measures to categorical approaches. Nevertheless, dimensional measures of severity and/or chronicity can provide important clues regarding how intensive treatment should be (e.g., watchful monitoring vs. psychotherapy vs. combined medication and psychotherapy, in the case of depressive symptoms; Klein, 2008).

The growth in the use of multivariate classification approaches in child and family assessment has been fueled by the extensive work of Thomas Achenbach and his colleagues (see the website for the Achenbach System of Empirically Based Assessment, *www.aseba.org*) with the various parent, teacher, youth, observer, and interview versions of the Child Behavior Checklist and Profile (Achenbach, 1993; Achenbach & Rescorla, 2001), and by the development of similar assessment batteries (e.g., the Behavior Assessment System for Children, Second Edition; Reynolds & Kamphaus, 2004). For a comprehensive discussion of these approaches and the use of empirically derived classification schemes more generally, the reader is referred to Achenbach (1993), Hart and Lahey (1999), and Mash and Barkley (2007).

It should also be noted that there has been a trend toward greater convergence of the categorical and dimensional approaches to classification. Many of the items that were retained in DSM-IV child categories were derived from findings from multivariate studies, and the process that led to the development of DSM-IV treated most childhood disorders as dimensions, albeit the use of cutoff scores on item lists arbitrarily created categories out of these dimensions (Spitzer et al., 1990). DSM-5 has continued this trend with a greater emphasis on dimensional measures of psychopathology across development.

Performance-Based Diagnostic Information

Performance-based information and/or observational measures provide additional sources of diagnostic information that may be sensitive to differences among children exhibiting similar self- or other-reported symptoms (Frick, 2000; Kazdin & Kagan, 1994). These measures assess children's performance on standardized tasks, usually ones that reflect basic biological, cognitive, affective, or social functioning.

For example, tasks involving behavioral observations of fear and avoidance, recall memory under stressful conditions, delayed response times to threatening stimuli, and the potentiation of the blink reflex following exposure to a threatening stimulus have all been suggested as potentially useful in diagnosing groups and/or subgroups of children with anxiety disorders (Kazdin & Kagan, 1994; Vasey & Lonigan, 2000). Similarly, tests of behavioral inhibition (e.g., the stop-signal paradigm) and tasks involving sustained attention (e.g., the continuous-performance test) have proven useful for research on children with ADHD (Rapport, Chung, Shore, Denney, & Isaacs, 2000). Measures of low resting heart rate as an early biological marker for later aggressive behavior (Raine, Venables, & Mednick, 1997); facial emotion recognition tasks and gambling tasks in identifying children with psychopathic tendencies (Blair, Colledge, & Mitchell, 2001; Blair, Colledge, Murray, & Mitchell, 2001); and a variety of cognitive tasks for children with autism spectrum disorder (Klinger & Renner, 2000) have also been found to have diagnostic value.

A study by Rubin, Coplan, Fox, and Calkins (1995) illustrates the utility of performance-based diagnostic information. These researchers differentiated groups of preschool children on the two dimensions of "emotionality" (i.e., threshold and intensity of emotional response) and "soothability" (i.e., recovery from emotional reaction based on soothing by self and others), and on their amount of social interactions with peers. Children's dispositional characteristics and behavioral styles were used to predict outcomes. Asocial children with poor emotion regulation had more internalizing problems. In contrast, social children with poor emotion regulation were rated as having more externalizing difficulties. When behavioral and emotional dimensions were incorporated into classification, it was possible to make finer predictions—for example, that only a certain type of asocial children (i.e., reticent children with poor emotion regulation) would display later problems.

The use of performance-based measures in diagnosis is predicated on the availability of reliable and valid performance indicators for groups of children with known characteristics. Although such data are available in varying amounts for a wide range of disorders, there is a need to validate such findings for the purposes of diagnosis and against other sources of information. It is also the case that performance criteria for these measures are based on information obtained from children who were themselves previously identified using other diagnostic procedures. This raises the question of nonindependence and representativeness of samples. There is also little normative information available regarding the base rates of children in the general population who exhibit certain patterns of responding on these tasks.

ISSUES IN CLASSIFICATION

Categories, Dimensions, or Both?

Psychological studies of child psychopathology have tended to conceptualize behavior, affect, and cognition on quantitative/continuous dimensions, whereas child psychiatry has tended to conceptualize child psychopathology in categorical terms. Both approaches are relevant to classifying childhood disorders, in that some disorders may be best conceptualized as qualitatively distinct conditions and others as extreme points on one or more continuous dimensions. However, there is ongoing debate regarding which childhood disorders are best conceptualized as categories and which as dimensions (Coghill & Sonuga-Barke, 2012). It has been suggested that many childhood disorders, such as anxiety, depression, ADHD, and the disruptive behavior disorders, appear to reflect dimensions of personality rather than categorical conditions (e.g., Werry, 2001). For example, childhood ADHD symptom clusters of inattention–disorganization and hyperactivity–impulsivity have been related to personality dimensions of low conscientiousness and low agreeableness, respectively (Nigg et al., 2001). Furthermore, children naturally vary in terms of their capacity to attend and in terms of how active they are (e.g., Rothbart, 2007), and in many other dimensional behaviors that overlap with clinical conditions (e.g., temperamental fearfulness and anxiety disorders—Goldsmith & Lemery, 2000; positive and negative emotionality and depression—Klein, Durbin, & Shankman, 2009). Even autism spectrum disorder, which has frequently been viewed as categorically distinct, can be conceptualized as an extreme version of a more normative style of approaching and understanding the world and other people (Baron-Cohen, 2000; Lawson, Baron-Cohen, & Wheelwright, 2004). For disorders that reflect underlying dimensions, the concern is that the practice of categorical diagnosis creates arbitrary distinctions between normality and abnormality (e.g., children who score just below the cutoff for a diagnosis may meet full criteria

at another assessment due to random fluctuations, and often show impairment comparable to that of children who meet full criteria). Since any classification scheme represents a construction rather than a reality, it seems unlikely that most disorders will fall neatly into one designation or the other (Lilienfeld & Marino, 1995). Whether or not particular conditions are construed as qualitatively distinct categories, as continuous dimensions, or as both will probably depend on the utility, validity, and predictive value of particular groupings and subgroupings for certain purposes related to understanding and remediating child psychopathology (e.g., Kendall, Brady, & Verduin, 2001). Regardless of the particular approach one adopts for the classification of childhood psychopathology, diagnostic decisions need to be based on a comprehensive assessment of the individual child—one that incorporates sensitivity to, and understanding of, the complexity of multiple antecedents, developmental considerations, comorbidity, continuity–discontinuity, and the constantly changing nature of the child (Frick, Barry, & Kamphaus, 2010; Mash & Hunsley, 2007). Given the general trend for cognitive-behavioral approaches to be the most effective available for childhood disorders (Mash & Barkley, 2006), functional analysis of child behavior should also play a key role.

Comorbidity

An issue that has important ramifications for theory and research in defining and classifying child psychopathology is comorbidity (Achenbach, 1995; Angold, Costello, & Erkanli, 1999; Carey & DiLalla, 1994; Caron & Rutter, 1991; Sonuga-Barke, 1998). "Comorbidity" generally refers to the manifestation of two or more disorders that co-occur more often than would be expected by chance alone. For example, although the base rates for ADHD and conduct disorder in the general population are less than 10% for each disorder, epidemiological studies have found that among children diagnosed with ADHD, approximately 50% are also diagnosed with conduct disorder (Kazdin & Johnson, 1994; Loeber & Keenan, 1994). Comorbidity has been reported to be high in community samples and even higher in clinic samples (Bird et al., 1988; Caron & Rutter, 1991; Costello, Mustillo, et al., 2003). Some of the more commonly co-occurring child and adolescent disorders include conduct disorder and ADHD, autism spectrum disorder and intellectual disability, and child/adolescent depression and anxiety disorders.

There is continuing debate regarding the definition and nature of comorbidity (Angold, Costello, & Erkanli, 1999; Blashfield, McElroy, Pfohl, & Blum, 1994; Cunningham & Ollendick, 2010; Lilienfeld, Waldman, & Israel, 1994; Meehl, 2001; Robins, 1994; Rutter, 1994b; Sameroff, 2000). Some researchers contend that the term is wholly inadequate because it does not distinguish accurately between manifest conditions seen in organic medicine (e.g., diseases) and latent conditions described in mental health (e.g., syndromes and disorders (Lilienfeld et al., 1994). Others argue that the dispute over whether one should use the term "comorbidity," "co-occurrence," or "covariation" is largely a semantic one (Rutter, 1994b; Spitzer, 1994; Widiger & Ford-Black, 1994).

Several possible reasons why comorbidity may be exaggerated or artificially produced have been identified in the literature (Angold, Costello, & Erkanli, 1999; Lilienfeld et al., 1994; Rutter, 1994b; Verhulst & van der Ende, 1993; Wolff & Ollendick, 2006). There may be a sampling bias that occurs when estimates of disorder prevalence are derived from treatment-seeking or clinic samples. In such cases, the clinic samples will contain a disproportionately large number of subjects who display comorbid conditions, as the probability of being referred to mental health services is higher for a child with a comorbid condition than for a child with only one disorder. Related to this sampling bias are various other referral factors that may inflate the degree of co-occurring disorders among clinic samples. Clinics and clinicians specializing in treatment of more complicated cases, for example, may be more likely to receive referrals in which comorbid conditions are present. In addition, children with internalizing difficulties such as depression are more likely to be referred by their parents or the school system if they also show externalizing symptoms, largely because externalizing problems are viewed as more disruptive by referral sources.

Comorbidity may also reflect various sources of nosological confusion arising from the manner in which different childhood disorders have been conceptualized and organized. For instance, Widiger and Ford-Black (1994) claim that excessive rates of co-occurrence seemed to appear concomitantly with the changes that occurred in DSM-III (e.g., increased coverage, divisions of diagnostic categories, the provision of separate and multiple axes). Another example is that DSM-5 makes it possible to have multiple diagnoses in the absence of multiple syndromes (Cantwell, 1996; Robins, 1994). One source of confusion stems from the overlap-

ping criterion sets within contemporary classification schemes (Drabick & Kendall, 2010; Rutter, 2010). In DSM-5, diagnoses are based on a set of polythetic criteria that include specific symptom constellations. In many cases, the presence of concomitant symptoms of a different kind are ignored, resulting in an increased likelihood that the accompanying symptoms will be represented in a different diagnostic category (Caron & Rutter, 1991). Sonuga-Barke (1998) argues, however, that although earlier diagnostic systems steered clear of comorbidity by using a hierarchical set of exclusionary criteria, "these approaches were abandoned because they clearly led to a misrepresentation of the structure of disorder" (p. 119). For example, they led to low base rates of disorders and poor interrater agreement.

Apart from the various artifactual contributors to comorbidity, there are also indicators in support of "true" comorbidity (Rutter, 1994b). It is possible that general propensities toward and/or struggles with adaptation are at the core of every disorder, but that the expression of the phenotype is contingent upon a myriad of environmental conditions and person–environment interactions (Caron & Rutter, 1991). Consistent with this notion, Lilienfeld and colleagues (1994) maintain that comorbidity in childhood disorders may be partly a function of developmental level—that is, of underlying processes that have not yet achieved full differentiation. Differing rates of comorbidity with age may also reflect the fact that the appearance of one disorder or problem may precede the appearance of the other, as is the case for anxiety preceding depression (Brady & Kendall, 1992) or for impulsivity preceding attentional problems (Hart et al., 1995). Still another possibility is that comorbidity reflects "a more amorphous early expression of psychopathology in young children that does not crystallize into more definitive psychopathology until later in life" (Cantwell, 1996, p. 4). Comorbidity can also arise as a result of a causal association in which the severity of one disorder may lead to or greatly increase the later risk for another disorder (e.g., ADHD and oppositional defiant disorder) or a shared underlying cause, such as common genetic influences (e.g., conduct disorder and depression) or neurobiological processes (e.g., anxiety and depression). In the case of shared etiology, poorly drawn boundaries between disorders may contribute to the appearance of multiple co-occurring disorders, when the reality is that two disorders are different manifestations of the same underlying neural circuit disruptions (Morris & Cuthbert, 2012).

In summary, it would appear that some cases of comorbidity are the results either of ambiguity in the definition of dysfunctionality that is used, or of artifactual/methodological issues. However, as Kazdin and Kagan (1994) note, "the broader point is still relevant and not controverted with specific diagnostic conundrums—namely, multiple symptoms often go together in packages" (p. 40). This is not to suggest that *all* disorders cluster together into packages; rather, the fact that many frequently do has important implications for how child psychopathology is conceptualized and treated. The complexity of comorbidity behooves researchers to move beyond singular models and to examine multiple expressions, etiologies, and pathways of childhood dysfunction (Beauchaine, Hinshaw, & Pang, 2010; Burt, Krueger, McGue, & Iacono, 2001; Kazdin & Johnson, 1994).

THE DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE

The developmental psychopathology perspective aims to provide a useful working framework for conceptualizing and understanding child psychopathology. This approach integrates multiple theories (e.g., psychodynamic, behavioral, cognitive, biological, family systems, and sociological), each of which focuses on different sets of variables, methods, and explanations (Achenbach, 2000), to provide a template and principles for understanding the processes underlying how and why psychopathology in children emerges, how it changes over time, and how it is influenced by a child's developmental capacities and by the contexts in which development occurs (Cicchetti & Toth, 2009). Long described as a macroparadigm that subsumes several theoretical approaches (Cicchetti, 1984; Cicchetti & Cohen, 1995; Lewis, 2000; Luthar et al., 1997; Rutter & Sroufe, 2000; Sameroff, 2000), "developmental psychopathology" has been defined as "*the study of the origins and course of individual patterns of behavioral maladaptation*, whatever the age of onset, whatever the causes, whatever the transformations in behavioral manifestation, and however complex the course of the developmental pattern may be" (Sroufe & Rutter, 1984, p. 18; original emphasis). Put simply, developmental psychopathology provides a general framework for understanding both normal development and its maladaptive deviations. Its main focus is an elucidation of developmental processes and their functioning through

an examination of extremes in developmental outcome and of variations between normative outcomes and negative and positive extremes. Developmental psychopathology does not focus exclusively on the study of childhood disorders, but serves to inform the understanding and treatment of disorders through the study of a full range of developmental processes and outcomes.

A developmental psychopathology perspective is consistent with both transactional and ecological views, and assumes that within ongoing change and transformation there exist coherence and predictability for adaptive and maladaptive development (Campbell, 1989; Cicchetti & Toth, 1997). This perspective also emphasizes the importance of endogenous (e.g., genetic, neurobiological) and exogenous (e.g., family, social, and cultural factors) and the interaction of the two in predicting and understanding developmental changes (Achenbach, 2000; Lewis, 2000). In this way, developmental psychopathology attempts to address the complex influences surrounding the development of the child across the lifespan. In attempting to do so, it draws on knowledge from multiple fields of inquiry (including psychology, psychiatry, sociology, education, criminology, epidemiology, and neuroscience) and attempts to integrate this knowledge within a developmental framework (Rutter & Sroufe, 2000).

The focus of developmental psychopathology is on normal developmental patterns, continuities and discontinuities in functioning, and transformational interactions over different developmental periods that produce adaptive or maladaptive outcomes. The processes underlying both healthy and pathological development are seen as stemming from idiosyncratic transactions between a child and his or her unique context (Achenbach, 2000; Sroufe & Rutter, 1984). Thus a central tenet of this approach is that to understand maladaptive behavior adequately, one needs to view it in relation to what may be considered normative for a given period of development (Edelbrock, 1984). Significant challenges for research, then, are to differentiate those developmental deviations that are within normative ranges from those that are not, and to ascertain which among the plethora of interacting variables account for developmental deviation. A developmental psychopathology perspective is also guided by several other principles, including the notion that the individual child plays an active role in his or her own developmental organization, that developmental outcomes are best predicted through consideration of prior experience and recent adaptations examined in concert, and that transitional turning points or sensitive periods in development represent times when developmental processes are most susceptible to positive and/or negative self-organizational efforts (Cicchetti & Tucker, 1994).

Until recently, the developmental psychopathology perspective has been more of a conceptual enterprise than a well-validated approach (Lewis, 2000). However, in a very short period of time, it has proven to be an enormously useful framework for understanding and guiding research in child psychopathology, and it represents an important shift in thinking away from single causal hypotheses toward a view based on complex and multiple pathways of influence: "After each effort to support an explanatory model by collecting a set of data, the results have required modifications in the model, forcing the field to evolve from a concern with causes and effects to an increasing appreciation of the probabilistic interchanges between dynamic individuals and dynamic contexts that comprise human behavior" (Sameroff, 2000, p. 297).

Within the integrative framework of developmental psychopathology, efforts are made to understand the different pathways through which similar forms of psychopathology emerge, and the reasons why seemingly similar developmental pathways may lead to different outcomes. Numerous disorder- and problem-focused theories have been proposed. These models are empirically based and are sensitive to the specific characteristics and processes that research has identified as important for understanding a particular disorder or problem. A few examples of representative models include Barkley's (2004, 2012a) theory of "inhibitory and executive dysfunction," which initially proposed behavioral inhibition as the primary and central deficit underlying the attentional, cognitive, affective, and social difficulties of children with ADHD. The subsequent iteration of this theory has now expanded this idea to include other executive functions, such as working memory, besides the inhibitory deficits as being central to this disorder (Barkley, 2004, 2012a). These initial deficits produce numerous effects at increasing spatial and temporal distances into the social ecology of the individual that comprise the extended phenotype of the disorder (Barkley, 2012b). Another example is the Cummings and Davies (1996, 2010; Davies & Cummings, 1994) "emotional security hypothesis," which proposes that emotional insecurity resulting from a number of sources (e.g., maternal depression, marital conflict) may lead to child difficulties in self-regulation, efforts to overregu-

late others, and maladaptive relational representations. Crick and Dodge's (1994) model of social information-processing deficits in aggressive children provides yet another example, which views aggression as a outcome of a child's use of biased or distorted interpretational processes in social situations.

Other theories that have been proposed to account for these and other problems and disorders are presented in the subsequent chapters of this volume. The growth in the number of such theories reflects an increasing trend toward models that focus on the processes underlying specific forms of child psychopathology, rather than on child psychopathology in general. However, most contemporary causal models that emphasize specific disorders have not conducted the necessary empirical tests to determine the specificity of putative etiological factors, despite the fact that that there are likely to be common factors (e.g., personality, genetic risks, family discord/stress) that increase risk for many different types of disorder (Epkins & Heckler, 2011). Identifying how etiological influences are similarly versus differentially related to disorders is an important task for future research.

GENERAL THEORIES OF CHILD PSYCHOPATHOLOGY

Several major theories have been proposed to account for the emergence of psychopathology in children (see Table 1.4). These include psychodynamic (Dare, 1985; Fonagy & Target, 2000; Shapiro & Esman, 1992), attachment (Atkinson & Goldberg, 2004; Bowlby, 1973, 1988), behavioral/reinforcement (Bijou & Baer, 1961; Skinner, 1953), social learning (Bandura, 1977, 1986), interpersonal (Gotlib & Hammen, 1992; Joiner & Coyne, 1999; Rudolph, Flynn, & Abaied, 2008); cognitive (Beck, 1964; Beck, Rush, Shaw, & Emery, 1979; Evraire, Dozois, & Hayden, in press; Ingram, Miranda, & Segal, 1998), constitutional/neurobiological (e.g., Cappadocia, Desrocher, Pepler, & Schroeder, 2009; Heim & Nemeroff, 2001; Matthys, Vanderschuren, & Schutter, 2013; Tripp & Wickens, 2009), affective (Davidson, 2000; Rubin, Cheah, & Fox, 2001), and family systems (Cowan & Cowan, 2002; Davies & Cicchetti, 2004; Grych & Fincham, 2001) models. A detailed discussion of the basic tenets of each of these general theories is beyond the scope of this chapter. For comprehensive discussions of these theories, the reader is directed to original sources and to specific references cited throughout this volume. What follows is a discussion of several general points related to some of these theories.

TABLE 1.4. General Models Used to Conceptualize Child Psychopathology

Psychodynamic models	Inborn drives, intrapsychic mechanisms, conflicts, defenses, psychosexual stages, fixation, and regression.
Attachment models	Early attachment relationships; internal working models of self, others, and relationships in general.
Behavioral/reinforcement models	Excessive, inadequate, or maladaptive reinforcement and/or learning histories.
Social learning models	Vicarious and observational experience, reciprocal parent–child interactions.
Interpersonal models	Interactional styles, social skills deficits, social difficulties, stressful interpersonal environments.
Cognitive models	Distorted or deficient cognitive structures and processes.
Constitutional/neurobiological models	Temperament, genetic influences, structural and functional neurobiological mechanisms.
Affective models	Dysfunctional emotion-regulating mechanisms.
Family systems models	Intra- and intergenerational family systems, and the structural and/or functional elements within families.

Note. Models are highlighted in terms of their relative emphasis.

Each general theoretical approach reflects a diversity of viewpoints. For example, psychodynamic theory encompasses traditional Freudian and Kleinian psychoanalytic constructs and their many derivatives as reflected in ego-analytic and object relations theory (Fonagy & Target, 2000; Lesser, 1972). Behavioral/reinforcement perspectives include traditional operant/classical conditioning constructs, mediational mod-

els, and contemporary theories of learning (Klein & Mower, 1989; Krasner, 1991; Viken & McFall, 1994). Cognitive theories include cognitive-structural models, models of cognitive distortion, and models of faulty information processing (Clark, Beck, & Alford, 1999; Ingram et al., 1998; Kendall & Dobson, 1993). Family systems theories include systemic, structural, and social learning models (Jacob, 1987). Therefore, when one is discussing any theory, it is critical to distinguish among the different perspectives encompassed by the approach.

Many theories of child psychopathology are derivatives of earlier approaches. For example, psychodynamic theories dominated thinking about child psychopathology for the first half of the 20th century. These theories contributed to our understanding of child psychopathology through their emphasis on the importance of relationships, early life experiences, mental mechanisms, and unconscious processes, and they spawned a number of other models—for example, attachment theory (Rutter, 1995). The emergence of attachment theory reflected a shifting of attention from the more traditional psychoanalytic role of intrapersonal defenses to that of interpersonal relationships (Bretherton, 1995). Similarly, the emergence of social learning theory reflected disenchantment with nonmediational models of learning and a growing interest in the role of symbolic processes.

A number of general points can be made regarding theories of child psychopathology:

1. Each theory offers an explanation regarding the etiology of child psychopathology. The strength of each theory rests on its specificity in predicting various forms of psychopathology and its degree of empirical support.

2. The varying degrees of support for each conceptualization suggest that no single model can fully explain the complexities involved in understanding child psychopathology. In light of this, increased understanding may accrue if greater integrative and collaborative efforts are undertaken.

3. Many explanations of childhood disorders implicitly or explicitly assume a simple association between a limited number of antecedents and a given disorder. However, as we have discussed, the concept of multiple pathways that lead to different outcomes depending on the circumstances represents a more viable framework in light of current research findings.

4. Although the testing of specific models is consistent with the spirit of parsimony, far greater attention needs to be given to the unique contexts and conditions under which a particular model does or does not apply.

5. Research on dysfunction frequently examines static conditions and influences such as the expression of a disorder at a given age or the influence of a specific stressor. However, evidence indicates that the expression and etiology of psychopathology in children are continuously changing over time, and theories need to account for these types of changes.

Current models are becoming increasingly sensitive to the many different components of childhood dysfunction. Indeed, constitutional, behavioral, cognitive, emotional, and social factors cross a number of theoretical domains; this is reflected in the emergence of hybrid models (e.g., cognitive-behavioral, social information processing, cognitive-neuropsychological), as well as the inclusion of family and ecological constructs across many different theories. Behavioral models, which have frequently been characterized as having a narrow emphasis on conditioning principles, are also becoming increasingly sensitive to systems influences (Viken & McFall, 1994).

Four interrelated theoretical approaches have received increased attention in current research on child psychopathology: (1) attachment theory, (2) cognitive theories, (3) emotion theories, and (4) constitutional/neurobiological theories. Each of these approaches is highlighted in the sections that follow.

Attachment Theory

Bowlby's (1973, 1988) theory of attachment is based on both an ethological and a psychoanalytic perspective (Cassidy & Shaver, 2008; Cicchetti, Toth, & Lynch, 1995). Nevertheless, Bowlby rejected the psychoanalytic ideas that individuals pass through a series of stages where fixation at or regression to an earlier state can occur, and that emotional bonds are derived from drives based on food or sex. Drawing on ethology and control theory, Bowlby and his successors replaced Freudian concepts of motivation based on psychic energy with cybernetically controlled motivational–behavioral systems organized as plan hierarchies (Bowlby, 1973; Bretherton, 1995). Within attachment theory, instinctive behaviors are not rigidly predetermined, but rather become organized into flex-

ible goal-oriented systems through learning and goal-corrected feedback. Motivational–behavioral systems (e.g., attachment, exploration) regulate time-limited consummatory behaviors and time-extended instinctive behaviors that maintain an organism in relation to its environment. Attachment belongs to a group of stress-reducing behavioral systems that operate in conjunction with physiological arousal-regulating systems. The child is motivated to maintain a balance between familiarity-preserving, stress-reducing behaviors, and exploratory and information-seeking behaviors. Self-reliance develops optimally when an attachment figure provides a secure base for exploration (Bretherton, 1995).

It is via the attachment relationship that the infant develops an "internal working model" of the self and others. Bowlby (1988) argued that the development of psychopathology is directly related to the inability of the caregiver to respond appropriately to the child's needs. This assertion is, however, a point of contention among researchers. Sroufe (1985), for example, has questioned the direct role of parental influence, arguing that infant temperament and the reciprocal interaction of a "difficult temperament" with parental response may better account for the variance in the attachment relationship and its ensuing insecure attachment difficulties. On the basis of a review of several studies examining infant temperament and attachment, Sroufe suggests that although some studies have supported the notion that differences between secure and insecure attachments may be due to temperament, the bulk of evidence suggests that infants change their attachment patterns with different caregivers.

In postulating an association between early attachment and later psychopathology, one must exercise caution, in that there does not appear to be one specific subtype of attachment that leads to one particular childhood disorder. Rather, the trajectory for developmental pathways and manifestations of psychopathology emerges as the result of environmental experience, biological predispositions, and learning. When one is identifying possible developmental paths as factors related to subsequent psychopathology, the concept of the child's internal working model is useful; however, it is important to bear in mind that the internal working model represents a set of active constructions that are subject to change, and that the association with later psychopathology is probabilistic rather than absolute.

Rutter (1995) has highlighted a number of key issues surrounding attachment, including (1) the need to identify mechanisms involved in proximity-seeking behavior; (2) broadening the basis for measuring attachment to include dimensions as well as categories; (3) studying relationship qualities that may not be captured by "insecurity"; (4) understanding the relationship between temperament and attachment; (5) dealing with how discrepant relationships are translated into individual characteristics; (6) operationalizing internal working models; (7) defining attachment quality across the lifespan, and determining whether or not meanings are equivalent at different ages; (8) determining how one relationship affects others; and (9) identifying the boundaries of attachment vis-à-vis other aspects of relationships. Several issues—the association between attachment and later functioning; the linkage between parenting and attachment quality; the adaptive value of secure attachment (e.g., insecure attachment does not equal psychopathology); disorders of attachment associated with abuse and neglect; and the diffuse attachments associated with institutionalization—are all in need of further investigation. Bowlby's attachment theory has played an important role in focusing attention on the quality of parent–child relationships, the interaction between security in relationships and the growth of independence, the importance of placing emergent human relationships within a biological/evolutionary context (e.g., Kraemer, 1992), the concept of internal working models, and insecure early attachments (e.g., Barnett & Vondra, 1999) as the basis for the development of psychopathology (Rutter, 1995).

Cognitive Theories

Considerable research has focused on the role of cognition (i.e., mental processes that include attention, memory, learning, problem-solving and decision-making) in both adult and child psychopathology (Clark et al., 1999; Ingram et al., 1998; Ingram & Price, 2001). Several theoretical perspectives have been concerned with childhood cognitions. These have included cognitive-structural models (Ingram et al., 1998; Selman, Beardslee, Schultz, Krupa, & Poderefsky, 1986), information-processing approaches (Crick & Dodge, 1994; Ingram & Ritter, 2000; Taylor & Ingram, 1999), and cognitive-behavioral approaches (Braswell & Kendall, 2001; Dobson & Dozois, 2001; Meichenbaum, 1977). Representative examples of the information-processing and cognitive-behavioral approaches are described below. Recently cognitive theories have focused on the importance of positive cognitions, the role of cognitive

specificity, the role of context on cognitions, the impact of comorbidity, the use of information-processing risk paradigms, a movement away from simple cognitive diathesis–stress models to looking at information-processing mediators, and the need for theoretical integration.

Information Processing

Biased information processing has been implicated in a number of childhood disorders. For example, socially aggressive children have been found to display negative attributional biases (Dodge & Pettit, 2003; Schwartz & Proctor, 2000); children with anxiety disorders show attentional biases to threatening stimuli (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van IJzendoorn, 2007; Waters, Henry, Mogg, Bradley, & Pine, 2010); and depressed children exhibit greater encoding biases for negative material, less endorsement and recall of positive information, and other forms of negative cognition (Abela & Hankin, 2008; Lakdawalla, Hankin, & Mermelstein, 2007). Research on information processing and child psychopathology has emanated from three streams: one focusing on deficits in basic information processing related to attention, memory, and other cognitive functions (e.g., Carter & Swanson, 1995); another related to social information processing (Crick & Dodge, 1994); and a third focusing on maladaptive cognition (e.g., Ingram et al., 1998; Ingram & Ritter, 2000; Taylor & Ingram, 1999).

Dodge's model as applied to socially aggressive boys illustrates the social information-processing approach (Dodge & Pettit, 2003; Dodge & Somberg, 1987). In the initial model, a series of thought processes and behaviors (i.e., encoding, interpretation, response search, response decision, and enactment) was postulated to occur during the course of appropriate social interactions and to be absent or distorted during inappropriate social interactions. The model has evolved, positing the same basic information-processing steps, but at each stage there is ongoing reciprocal interaction between the information-processing skills required during social transactions in context and the individual's "database" (a collection of social schemas, memories, social knowledge, and cultural values or rules) (Crick & Dodge, 1994; Dodge & Pettit, 2003). Instead of a linear processing model, there are postulated to be cyclical feedback loops connecting all stages of processing. Increased recognition of the influence of peer appraisal and response, emotional processes, and the development and acquisition of cognitive skills as important contributors to social adjustment are meaningful additions to the reformulated model. In addition to the enhanced sensitivity to developmental trajectories, the reformulated model emphasizes the role of early dispositions (e.g., temperament) and other factors (e.g., age, gender, social context) that serve to moderate the relationship between information processing and social adjustment. A number of studies have provided empirical support for the expanded model (Contreras, Kerns, Weimer, Getzler, & Tomich, 2000; Gomez & Gomez, 2000; Gomez, Gomez, DeMello, & Tallent, 2001).

Cognitive-Behavioral Theories

Cognitive-behavioral theories represent "a purposeful attempt to preserve the positive features of the behavioral approaches, while also working to incorporate into a model the cognitive activity and information-processing factors of the individual" (Kendall & MacDonald, 1993, p. 387; see also Braswell & Kendall, 2001), and cognitive vulnerabilities to depression and anxiety in particular are firmly established as central models of risk and treatment. Research on such cognitive models initially focused on adults, using a wide array of operationalizations of cognitive risk; this research has generated a vast corpus of results generally supporting the central tenets of cognitive theories, in that cognitive vulnerability has been found to be a diathesis that interacts with negative life events to predict increases in symptoms (Ingram et al., 1998).

Four elements of cognition are distinguished for the purpose of understanding the pathogenesis of psychiatric disturbances: cognitive structures, content, operations, and products (Beck et al., 1979; Dozois & Dobson, 2001; Ingram et al., 1998; Kendall & Dobson, 1993). "Cognitive structures" represent the way in which information is organized and stored in memory, and serve the function of filtering or screening ongoing experiences. "Cognitive content" (or propositions) refers to the information that is stored in memory (i.e., the substance of the cognitive structures). Together, cognitive structures and content make up what is termed a "schema." A schema stems from a child's processing of life experiences and acts as a guideline or core philosophy influencing expectations and filtering information in a fashion consistent with the child's core philosophy. As such, cognitive schemas have also been referred to as "filters" or "templates" (see Kendall & MacDonald, 1993). A schema is postulated to affect the relative ob-

served consistency in the child's cognition, behavior, and affect (Stark, Rouse, & Livingston, 1991). According to Beck's model, maladaptive schemas develop in early childhood and remain dormant until some untoward event triggers the latent schemas, and the individual begins to encode, process, and interpret information in a schema-congruent way. Individuals with a depression schema, for instance, process and interpret information about themselves, the world, and the future in a negatively biased fashion, whereas persons with an anxiety schema interpret environmental stimuli with a cognitive focus on future threat. In addition, what appears to be specific to depression is a lack of positive cognition (Gencoez, Voelz, Gencoez, Pettit, & Joiner, 2001). "Cognitive processes" or "cognitive operations" pertain to the manner by which the cognitive system functions. Thus cognitive processes, which are guided by schemas, suggest the mode by which an individual perceives and interprets both internal and external stimuli. Finally, "cognitive products" are the ensuing thoughts that stem from the simultaneous and reciprocal interactions among the various components of the cognitive system.

Work testing cognitive models of depression has shifted in recent years toward the exploration of the utility of these models in adolescents and children (Abela & Hankin, 2008). Reviews of this literature support the claim that cognitive vulnerability in youth is an important prospective predictor of depressive symptoms (e.g., Hankin et al., 2009), usually when examined in conjunction with stressful life events. More specifically, most studies have focused on testing whether the interaction between negative cognition and stress predicts elevations in children and adolescents' depressive symptoms. These studies have shown that stressful life events show stronger associations with depression when youth possess negative cognitive styles (such as maladaptive attributional styles), information-processing biases favoring enhanced processing of negative stimuli, and other aspects of depressive cognition (Abela & Hankin, 2008; Lakdawalla et al., 2007).

A potentially useful distinction can be made between "cognitive deficits" and "cognitive distortions." Kendall (1993) argues that this distinction is useful in describing, classifying, and understanding a variety of juvenile disorders. Children with "deficits" display an absence of thinking where it would be beneficial. Aggressive youth, for example, frequently lack the ability to encode interpersonal information (Coy, Speltz, DeKlyen, & Jones, 2001; Pakaslahti, 2000; Schwartz & Proctor, 2000) or to solve social problems adequately (Crick & Dodge, 1994; Lochman & Dodge, 1994), and impulsive children often fail to think before they respond (Moore & Hughes, 1988). Conversely, children who display "distortions" typically do not lack the ability to organize or process information; rather, their thinking is described as biased, dysfunctional, or misguided (Kendall, 1993; Kendall & MacDonald, 1993). A depressed individual's negative view of him- or herself, the world, and the future is an example of distorted thinking. Kendall (1985, 1993) notes that the distinction between deficient and distorted thinking is relevant to the distinction that has been made between externalizing and internalizing disorders (cf. Achenbach, 2000). Generally, internalizing disorders are related to distortions in thinking, whereas externalizing disorders are more commonly associated with cognitive deficits. However, empirical evidence suggests that aggressive behaviors usually include both distortions and deficits (e.g., Lochman, White, & Wayland, 1991).

Cognitive models have both strengths and weaknesses. The theoretical model asserts that stable, latent schemas develop in childhood and are dormant until a triggering negative event; the model thus generates strong hypotheses regarding the assessment of cognitive risk and the work of therapy (Braswell & Kendall, 2001; Kendall, 1993). Importantly, these theories thus assert the stability of cognitive risk markers that emerge early in life. There is ongoing debate regarding when meaningful, stable aspects of cognitive vulnerability emerge (e.g., Abela & Hankin, 2011; Cole et al., 2008; Garber, 2010; Gibb & Coles, 2005; Hammen & Rudolph, 2003). Furthermore, work that speaks to the stability of childhood cognitive vulnerability is accruing (e.g., Cole et al., 2009: Hankin, 2008; Hayden, Olino, Mackrell, et al., 2013), and evidence is consistent with both stability and change (Hankin et al., 2009). This literature indicates that while some rank-order stability emerges in later childhood, significant change also occurs for some children. However, this work has focused on self-reported cognitive risk in later childhood and early adolescence, and across relatively brief follow-ups—factors that may serve to indicate increased stability compared to research on younger samples using laboratory-based measures and longer follow-up intervals. Further work on emerging cognitive risk in younger children, indexed via approaches that map more fully onto the array of methodologies indexing cognitive risk in depression, is clearly needed. If a period in development can be identified in which

children's cognitive vulnerability has both meaningful implications for disorder risk *and* evidence of some degree of plasticity, such a period could represent an important window for preventative efforts.

Another limitation of these models is that the developmental origins of emerging cognitive risk have yet to be fully explored, particularly in the context of broader models childhood cognitive risk. More specifically, relatively little research has attempted to identify early precursors of negative cognition implicated in disorder risk. In recent years, work tying negative cognition to early adversity (Gibb, 2002), parental psychopathology, emotional traits (Davidson et al., 2002; Hamburg, 1998; Hayden et al., 2006), and genetic risk (Gibb, Beevers, & McGeary, 2013; Hayden, Olino, Bufferd, et al., 2013) has begun to emerge, although more comprehensive models that test the possibility of dynamic interplay among multiple factors are still lacking.

Emotion Theories

Emotion and its regulatory functions are constructs that cross several conceptual models— including psychodynamic theory, with its concept of defense mechanisms; cognitive-behavioral theory, which stresses the role of thought patterns and behavior as determinants of emotion; attachment theory, with its premise that an internal working model is formed on the basis of early relations and continues to regulate emotion in subsequent relationships (Cassidy, 1994); and biological theories, which emphasize the structural and neurochemical correlates of emotion regulation (Pennington & Ozonoff, 1991; Posner & Rothbart, 2000). Emotion and its regulation played a central role in the conceptual paradigms of early models of child psychopathology. For example, psychoanalytic theory emphasized the regulation of emotions through the use of defense mechanisms, with an absence of such regulation leading to anxiety and psychopathology (see Cole, Michel, & Teti, 1994). By giving individuals the opportunity to avoid, minimize, or convert emotions, defense mechanisms were hypothesized to serve the function of regulating emotional experiences too difficult to manage at the conscious level.

Although the advent and growth of cognitive and behavioral models shifted attention away from an interest in affective processes, the study of emotional processes in child psychopathology has experienced a resurgence of interest (Arsenio & Lemerise, 2001; Belsky, Friedman, & Hsieh, 2001; Insel, 2003; Rubin et al., 2001), in recognition that children's emotional experience, expression, and regulation are likely to affect the quality of their thinking, social interactions, and relationships (e.g., Flavell, Flavell, & Green, 2001; Rubin et al., 2001; Schultz, Izard, Ackerman, & Youngstrom, 2001). From a functionalist perspective, emotions are viewed as playing a causal role in organizing and directing the way in which children react to environmental events. This perspective is illustrated by findings showing that induced negative child emotions increase children's distress, negative expectations, and appraisals of adult conflict, whereas induced positive emotions have the opposite effect (Davies & Cummings, 1995). Several discussions have focused on the development of emotion regulation and its ability to influence both adaptive and maladaptive functioning (Fredrickson, 2001; Kagan, 1994b; Mayer & Salovey, 1995; Thompson, 2011). In general, there is growing support for the view that emotionality and regulation are related to children's concurrent and long-term social competence and adjustment (Eisenberg, Fabes, Guthrie, & Reiser, 2000).

Emotion systems have as their primary functions the motivation/organization of behavior and communication with self and with others. Emotions represent patterns that include at least several of the following components: (1) activating neural, sensory–motor, cognitive, and/or affective stimulus events; (2) dedicated neural processes; (3) changes in physiological responses; (4) changes in motoric/expressive behavior; (5) related cognitive appraisals; and (6) concomitant alterations in subjective experiences or feeling states (Cicchetti, Ackerman, & Izard, 1995; Izard, 1993; Kagan, 1994b).

Different theories have viewed child psychopathology as emanating from the following: (1) unrestrained emotions (i.e., emotions that are unconnected to cognitive or affective–cognitive control processes); (2) deficits or distortions in cognitions and behaviors that interfere with emotion modulation (i.e., emotions connected to cognitive processes and behavior that are situationally inappropriate); (3) emotional interference with planful cognitive processes (i.e., emotional flooding); (4) dysfunctional patterns of emotion processing and communication, involving problems with recognition, interpretation, and expression; and (5) difficulties in coordinating emotional and cognitive processes in the regulation of emotion (Cicchetti, Ackerman, & Izard, 1995).

Emotion dysfunction may emanate from several sources, including variations in biological vulnerabil-

ity and stress. In studying child psychopathology, it is important not to focus on negative emotions without also recognizing several other factors: the beneficial and buffering effects of positive emotions (Fredrickson, 2001; Masten, 2001; Tugade & Fredrickson, 2004; Wichers et al., 2007); the adaptive value and facilitating effects of negative emotions of moderate or at times even extreme intensity; and the ongoing importance of emotion content and meaning for a child's behavior. Also, since negative emotions are neither topographically nor functionally unidimensional, it is important to identify the *discrete* emotions and emotional patterns underlying different forms of child psychopathology (Cicchetti, Ackerman, & Izard, 1995). For example, the negative affect that is associated with depression may involve sadness, anger, or guilt, in the same way that negative behaviors in depressed children may be both aggressive/confrontational and depressive/distressed (Hops, 1995).

It may be useful to distinguish between the two dimensions of "emotion reactivity" and "emotion regulation." "Reactivity" refers to individual differences in the threshold and intensity of emotional experience, whereas "regulation" describes processes that operate to control or modulate reactivity (e.g., attention, inhibition, approach–avoidance, coping styles) (Rubin et al., 1995). According to Rubin and colleagues (1995), this distinction is important because it highlights the need to focus on the dynamic interaction between general temperament and specific regulatory mechanisms, and in turn the need to recognize that emotional arousal (reactivity) can serve to inhibit, facilitate, or disrupt behavior. The distinction can also be made between problems in regulation and problems in dysregulation, with regulation problems involving weak or absent control structures or structures overwhelmed by disabling input, and dysregulation involving existing control structures that operate in a maladaptive manner and direct emotion toward inappropriate goals (Cicchetti, Ackerman, & Izard, 1995). Functions of emotion involve the emotion knowledge of self and others in identifying feelings and behavior, including monitoring of self and environment. Absent or weak monitoring may result in dissociated emotional and cognitive processes and emotional leakage, whereas excessive monitoring may lead to a narrow sampling of emotional signals and excessive use of specific emotions in communication (Cicchetti, Ackerman, & Izard, 1995).

Of interest to the present chapter is the manner in which emotion regulation has been defined and conceptualized with respect to psychopathology (Keenan, 2000). The processes of emotion regulation include the attenuation or deactivation of an ongoing emotion, the amplification of an ongoing emotion, the activation of a desired emotion, and the masking of emotional states (Cicchetti, Ackerman, & Izard, 1995). Thompson (1994) defines emotion regulation as consisting of "the extrinsic and intrinsic processes responsible for monitoring, evaluating, and modifying emotional reactions, especially their intensive and temporal features, to accomplish one's goals" (p. 27). This definition highlights several important characteristics of emotion regulation. First, it involves enhancing, maintaining, or inhibiting emotional arousal for the purpose of meeting one's goals. Second, there are both internal and external factors that influence the development and use of emotion-regulating strategies. Finally, there is a temporal dimension: Sometimes there are sudden and transitory changes in emotional arousal that must be dealt with (e.g., acute or state anxiety), whereas at other times there are longer-lasting ramifications of emotional arousal created by years of experience (e.g., chronic or trait anxiety; Kagan, 1994b; Terr, 1991). However, an important conceptual issue that is central to the question of what is currently known about the role of emotion regulation in child development and psychopathology concerns the extent to which research has adequately differentiated between emotion experience (i.e., the strength of an initial emotional response) and regulatory processes (i.e., processes that modulate this initial response). Although emotion and emotion regulation are theoretically distinct, Campos, Frankel, and Camras (2004) have cogently argued that the processes that underpin the two overlap almost entirely, and that adequately differentiating between them for the purposes of assessment is a potentially intractable problem. Indeed, a review of the literature indicates that many studies methodologically conflate high emotionality (e.g., the expression of high levels of negative emotions) with deficits in regulatory processes by using indicators that apply to both constructs (see Lewis, Zinbarg, & Durbin, 2010, for an eloquent discussion of these considerations). In order for a better understanding of the incremental utility of emotion regulation for psychopathology to emerge, greater efforts to differentiate it from near-neighbor constructs are essential.

The development of emotion regulation or dysregulation is thought to derive both from innate predispositions and from socialization. At the level of constitutional factors are various neural circuits and temperamental

characteristics. For example, inhibited children appear to bring a high state of reactivity into their environment, particularly in novel or unfamiliar situations. This biological propensity is thought to be the result of a number of neurological factors that include interrelating messages sent to and from neuroanatomical structures (vis-à-vis neuroelectricity and neuropharmacology) to the central and peripheral nervous system (Fox, Henderson, Marshall, Nichols, & Ghera, 2005). Cognitive and language development also contribute to emotion regulation. Growth in cognitive development allows the child increasingly to differentiate and cope with a diverse set of emotion-arousing stimuli. The development of emotion language also affords an opportunity for the communication of emotion meaning to others and its management through self-regulatory mechanisms (Cole et al., 1994; Thompson, 1994).

Finally, emotion regulation is also embedded within the unique context of the child. Socialization influences within the family, peer group, and culture are important in the development and expression of emotion, and may support or hinder emotion regulation in a variety of ways. One important influence is the way in which parents respond to the child's initial expressions of emotion, and how emotions are communicated in the context of the ongoing interactions between the parents and child (Cassidy, 1994; Volling, 2001). The development of emotion regulation may also come about through the modeling of appropriate or inappropriate emotional expression (e.g., Shipman & Zeman, 2001). Finally, the rules or boundaries of emotional expression, which are established by both the family and the community at large, also influence the development of emotion regulation (Cole et al., 1994).

Emotion dysregulation begins with context-specific efforts at self-regulation, which may then develop into more stable patterns of responding and thereby contribute to the development of psychopathology. The determination of emotion regulation as adaptive or maladaptive varies with the circumstances, but it generally involves the degree of flexibility of the response, the perceived conformity of the response to cultural and familial rules and boundaries, and the outcome of the response relative to the child's and parents' short- and long-term goals (Thompson, 1994).

Some forms of emotion dysregulation may be adaptive in one environment or at one time, but maladaptive in other situations or at other points in development (Fischer et al., 1997; Thompson & Calkins, 1996). For example, in discussing children who have been emotionally and sexually abused, Terr (1991) describes the process of "numbing" (a symptom of a posttraumatic stress reaction), which serves to protect a child from overwhelming pain and trauma. However, when numbing becomes a characteristic way of coping with stressors later in life, it may interfere with adaptive functioning and with long-term goals. Another example stems from studies on attachment quality. In response to attachment figures that are rejecting or inconsistent, infants may develop an insecure/avoidant attachment in which emotional expression is minimized. Such an infant's reduced emotional expression, while serving the strategic function within the attachment relationship of minimizing loss by reducing investment in the relationship, may establish a pattern of emotional responding that is maladaptive for the development of subsequent relationships (Cassidy, 1994).

In summary, emotion theorists conceptualize the development of emotion regulation as involving a variety of increasingly complex developmental tasks. The degree of interference with these tasks depends on the characteristics of the child and his or her environment, as well as on their interaction. Emotion dysregulation is believed to be the consequence of interference in the associated developmental processes. Dysregulation is associated with a wide range of emotions; depending on the overall context, it may or may not become a stylistic pattern, and it may or may not lead to later psychopathology.

Genetic/Neurobiological Theories

In attempting to understand child psychopathology, genetic/neurobiological theorists recognize individual differences in genetically based, neurobiological characteristics and processes. From this perspective, mental disorders are represented in the brain as a biological entity (Insel et al., 2010). The goal of research in this field is therefore to characterize the genetic, structural, and functional brain bases of psychopathology. Diverse lines of research, including family and twin studies, molecular genetic, neurobiological, neurophysiological, and neuroanatomical studies, suggest a heritable, neurobiological basis for many childhood disorders, including ADHD, autism spectrum disorder, adolescent depression, pediatric bipolar disorder, social withdrawal, some anxiety disorders, and obsessive–compulsive disorder, to name a few. Research on brain structure and function using neuroimaging procedures has implicated specific brain regions for ADHD (e.g., Frodl

& Skokauskas, 2012; Peterson et al., 2009), anxiety disorders (De Bellis et al., 2002; McClure et al., 2007), autism spectrum disorder (Di Martino et al., 2009), and many other disorders, as reviewed in subsequent chapters. There is also increasing interest in neural network perspectives on disorder, as few disorders (if any) arise from a single brain region; such work has aimed to characterize both functional (Gaffrey, Luby, Botteron, Repovš, & Barch, 2012) and structural connectivity (e.g., Zielinski et al., 2012) between brain regions that work in conjuction to influence processes relevant to psychopathology (e.g., self-referential processing; Hamilton et al., 2011).

Neuroimaging studies tell us that one region or another may be involved, but they do not tell us why, and the findings for particular disorders are not always consistent from study to study, for children of different ages, or for boys versus girls. Furthermore, much of this work has failed to meet the standards of other types of research in the field of developmental psychopathology. For example, very little neuroimaging research adequately disentangles the time course by which disorder is linked to brain structure and function (i.e., differences in brain structure and activity can emerge as both causes and consequences of a disorder; longitudinal work is needed to address this possibility). In addition, many of these studies have used small samples, and other methodological inconsistencies raise questions about the robustness of some findings (Vul & Pashler, 2012). Research into specific neurotransmitters has also provided promising leads, although findings have also been inconsistent. One of the difficulties in research in this area is that many forms of child psychopathology involve the same brain structures and neurotransmitters, making it difficult to assess the specificity of their contributions to particular disorders. Such findings may reflect the limitations of existing categorical diagnostic systems, as discussed earlier in the section describing the RDoC initiative (Insel et al., 2010).

With respect to genetic influences on child psychopathology, familial aggregation has been viewed as an important initial step in providing evidence for genetic mechanisms. Once familial clustering is demonstrated, twin studies, adoption studies, segregation analyses, and linkage studies can be conducted (cf. Szatmari, Boyle, & Offord, 1993). "Familial aggregation" refers to the nonrandom clustering of disorders or characteristics within a given family, relative to the random distribution of these disorders or characteristics in the general population (Szatmari et al., 1993). This paradigm rests on the premise that if there is a genetic component to a given disorder, the frequency of the phenotype (or manifest pathology) will be higher among biological relatives of the proband than in the general population (Lombroso, Pauls, & Leckman, 1994).

Twin studies are beneficial in helping to ascertain the contribution of genetic factors in the etiology of child psychopathology. The twin study approach emerged from the long-standing "nature versus nurture" or "genes versus environment" debate (Lombroso et al., 1994). Although twin studies provide a powerful research strategy for examining the role of genetic influences in both psychiatric and nonpsychiatric disorders, numerous methodological issues necessitate that caution be exercised in interpreting findings. For example, although Willerman (1973) found a concordance rate for hyperactivity of approximately 70%, this does not necessarily mean that 70% of the variance in hyperactivity is accounted for by genetic variation. Research suggests, for instance, that monozygotic twins spend more time together, frequently engage in similar activities, and have many of the same friends in common (Torgersen, 1993). Thus the common or shared environment presents a potential confound in any twin study, and unless twins are reared apart, or dizygotic twins are employed as the comparison group, it becomes difficult to separate the effects of genetic and environmental influences. Moreover, mutations can occur very early in cell proliferation in one twin fetus that result in phenotypic discordance (Czyz, Morahan, Ebers, & Ramagopalan, 2012). While such differences are clearly of genetic origin, they would be classified as "environmental" in parsing the variance in the trait under study. Representativeness and generalizability to the general population are other problems with twin studies (Lombroso et al., 1994; Torgersen, 1993). Growing up with a sibling of an identical age, for example, introduces its own special challenges (e.g., competition between siblings, greater dependency on each other) that make the twin environment unique.

Adoption studies have been used to circumvent some of the problems with twin and familial aggregation studies. They explicitly attempt to control for environmental variation in the heritability equation. The assumption behind this strategy is that when a disorder has a genetic etiology, the frequency of its expression should be greater among biological relatives than among adoptive relatives. Conversely, when environmental factors assume a larger role in the etiology of

psychopathology, the frequency of the disorder would be expected to be greater among the parents of adoptive relatives than among biological parents (Lombroso et al., 1994; Torgersen, 1993).

Several reasons may be advanced to account for the sparse number of investigations using the adoptive strategy. One obstacle has been the difficulty of obtaining reliable information regarding the biological parents of adoptees. The timing of adoption placements also represents a potential confound. Since children are typically adopted at different ages, it is difficult to determine what environmental influences the biological parents may have had during the earliest years of life (Lombroso et al., 1994). Similarly, many children are placed in residential settings prior to adoption; these conditions, which may affect a child's development, would be unaccounted for by an adoptive strategy. A confound analogous to the problem of timing is the high probability of being placed in an adoptive home that is similar to the home environment of the biological family. For instance, adoption agencies are quite strict in their criteria for adequate placements, and the adoptive home must, at a minimum, meet current middle-class standards (Torgersen, 1993).

However, while the aforementioned designs (i.e., family, twin, and adoption studies) play a vital role in providing evidence for the heritability of a disorder, and thus laying the groundwork for future research on genetic etiology, they are not equipped to identify specific genetic variants that play a role in the pathogenesis of disorder. The identification of etiologically relevant genes (i.e., those implicated in the pathophysiology of disorder) has the potential to greatly enhance our understanding of a disorder, as well as potential treatment mechanisms (Stodgell, Ingram, & Hyman, 2000). Toward this goal, the past few decades have witnessed rapid advances in researchers' ability to derive vast amounts of information on individual differences in genetic factors potentially relevant to disorder risk, and psychopathologists have accordingly availed themselves of these technologies. As a result, specific genetic variants have been implicated in virtually all forms of psychopathology (e.g., Allen et al., 2008; Gizer, Ficks, & Waldman, 2009; Levinson, 2006).

Unfortunately, replication of molecular genetic findings remains a significant concern, and there is disagreement regarding the best way forward in the search for the genetic bases of psychopathology (Hudziak & Faraone, 2010; Willcutt et al., 2010). Concerns raised in regard to efforts to model links between single genes and disorder include (1) the fact that such designs fail to capture the polygenic basis of psychopathological phenomena; (2) the arguably low likelihood that diagnostic syndromes are adequate phenotypes for molecular genetic study; (3) the probability that some variants operate in a context-dependent manner (i.e., the case of gene–environment interaction, or G×E); relatedly, (4) the fact that gene function is a dynamic phenomenon influenced by the environment, other genetic variants, and multiple epigenetic processes not captured by studies that assess genotype–phenotype associations only; and (5) the possibility that many cases of disorder are related to yet-to-be identified rare variants, making the a priori selection of candidate genes misguided. We address these points in the following few paragraphs.

Genome-wide association studies have emerged as a means of capturing polygenic influences on psychopathology, although their replication record appears variable, and overall effect sizes have been criticized for their small magnitude (Manolio, 2010; McCarthy et al., 2008); furthermore, it is unclear how to incorporate such studies within frameworks that also capture environmental influences on disorder, as well as G×E. With respect to concerns regarding the use of diagnostic phenotypes, many investigators interested in the molecular basis of disorder elect to avoid the use of these entirely, focusing instead on endophenotypes (Gottesman & Gould, 2003), or markers of disorder risk that are thought to lie more proximal to the actions of genes than diagnostic outcomes. For example, endophenotypes related to neuropsychological function (such as reaction time variability, time reproduction, and response inhibition) have been applied to the genetic investigation of ADHD (e.g., Nigg, 2010), and biases in memory may be a promising endophenotype for depression risk (e.g., Hayden et al., 2006; Hayden, Olino, Bufferd, et al., 2013), although variability across studies in terms of how endophenotypes have been operationalized has made replication attempts difficult.

Regarding the conditional effects of genes, one of the more controversial directions in psychiatric genetics is the emergence over the past decade of studies testing G×E, which attempt to capture the interplay between specific genetic variants and environmental risk factors in producing psychopathological outcomes (Kendler, 2011; Uher, 2011). Although the earliest of these seminal studies focused on psychiatric disorder in adults (e.g., Caspi et al., 2003), this literature has frequently focused on the role of early childhood adversity in potentiating the effect of genetic risk variants on

later disorder; this may account for the tremendous appeal of this approach to developmental psychopathologists, who tend to have a keen interest in the dynamic relationship between endogenous child and contextual risk factors. Moreover, studies identifying G×E hold the promise of accounting for the poor rate of replication of studies seeking to identify single-gene main effects, if many genetic influences are context-dependent or conditional. It is therefore not surprising that journals have been flooded with studies testing G×E across development.

Unfortunately, many of these studies are plagued by the same limitations found in poorer-quality molecular genetic association studies (e.g., small sample sizes; testing genetic influences on relatively complex, biologically implausible phenotypes), and may represent false-positive findings (Duncan & Keller, 2011). Also, attempts to model single-gene effects on complex psychiatric phenotypes, even within the context of environmental risk, may be misplaced. For many of the more popular G×E models, meta-analyses have been conducted that have supported (Karg, Burmeister, Shedden, & Sen, 2011; Kim-Cohen et al., 2006) and refuted (e.g., Risch et al., 2009) these findings. It has been argued that poor measurement approaches (e.g., self-report questionnaires) to the phenotype and the environmental context limit the ability of studies to detect true G×E (Monroe & Reid, 2008). Furthermore, Brown (2012) recently noted that studies of adults in which support for a G×E involving the serotonin transporter genotype and stress was evident were those in which adult stress could be interpreted as a marker of childhood adversity, suggesting that research on G×E should focus on developmental periods of greater plasticity (i.e., childhood), as this is when environmental moderation of genetic effects is unfolding. In conclusion, while it seems unquestionable that genetically influenced responses to the environment are an important force in risk for psychopathology, the question of how best to model this interplay has yet to be resolved.

Aside from these concerns, few would argue that the fact that studies of G×E are attempting to model an unknown, underlying biological process through statistical methods is an unimportant limitation. In other words, tests of G×E statistically model the conditional effects of genes without knowledge of the biological mechanisms through which these conditional effects emerge (Mill, 2011). While accurate genotyping of the loci implicated in psychopathology risk is now relatively affordable, a host of dynamic processes (see Mill, 2011, for an overview of these) known as "epigenetic influences" that further shape the actions of genes are less well understood or readily characterized to date, although these appear to play a more important role in gene function than previously thought. An emerging body of research is exploring epigenetic markers in psychiatric disorders and related processes in humans (Petronis, 2010); however, it is unclear whether the noninvasive methods available for human epigenetic research adequately reflect epigenetic processes in the human brain, which are presumably the most relevant to mechanisms of psychopathology.

Finally, it has been argued that, in sharp contrast to the widely held notion that disorder arises from the summed influence of many genes with small individual effects, individual rare variants with a large, harmful impact on neural function play a key role in the genetic basis for psychiatric disorder (McClellan & King, 2010). Although such rare variants by definition do not account for a large number of cases of disorder, the hope is that through their study, a better understanding of the pathophysiology of disorder can be gained. This is a relatively new approach that, due to its novelty, is difficult to evaluate in terms of the insights it has yielded to date.

SUMMARY AND CONCLUSIONS

In this introductory chapter, we have described a developmental–systems framework for child psychopathology that emphasizes three central themes: (1) the need to study child psychopathology in relation to ongoing normal and pathological developmental processes; (2) the importance of context in determining the expression and outcome of childhood disorders; and (3) the role of multiple and interacting events and processes in shaping both adaptive and maladaptive development. The research findings presented in the subsequent chapters of this volume illustrate the importance of these themes for understanding children and adolescents displaying a wide range of problems and/or disorders.

A developmental–systems framework eschews simple linear models of causality and advocates for a greater emphasis on systemic and developmental factors and their interactions in understanding child psychopathology. Multiple etiologies and their interplay represent the norm for most forms of child psychopathology. For example, in the study of conduct disorder, genetic in-

fluences, constitutional factors, insecure attachment relationships, impulsivity, biased cognitive processing, parental rejection, a lack of parental supervision, interpersonal difficulties, and many other influences have been implicated. However, many of these influences have also been implicated in other disorders, and not all children who exhibit such risks develop conduct disorder. There is a need for research that will help to disentangle the role of these multiple sources of influence and their interactions in relation to different childhood disorders.

We have argued that all forms of child psychopathology are best conceptualized in terms of developmental trajectories, rather than as static entities, and that the expression and outcome for any problem will depend on the configuration and timing of a host of surrounding circumstances that include events both within and outside a child. For any dynamically changing developmental trajectory, there also exists some degree of continuity and stability in structure, process, and function across time. Understanding such continuity and stability in the context of change represents a challenge for future research; it necessitates that psychopathology in children be studied over time, from a number of different vantage points, utilizing multiple methods, and drawing on knowledge from a variety of different disciplines.

Given the complexities associated with a developmental–systems framework for understanding child psychopathology, there is a clear need for theories to guide our research efforts. We have argued that a developmental psychopathology perspective provides a broad macroparadigm for conceptualizing and understanding childhood disorders in general, and that complementary disorder- and problem-specific theories are also needed to account for the specific configurations of variables commonly associated with particular disorders. Such problem-specific theories are presented in the subsequent chapters of this volume. The conceptualization of child psychopathology in terms of developmental trajectories, multiple influences, probabilistic relationships, and diverse outcomes suggests that some influences are likely to be common to many different disorders and that others are probably specific to particular problems. Our theories need to account for both types of influence.

As we have seen, childhood disorders constitute a significant societal problem, and in the absence of an empirically grounded knowledge base, unsubstantiated theories have frequently been used as the basis for developing solutions to these problems. There is a pressing need for further longitudinal research to inform our intervention and prevention efforts. If such work is to succeed in capturing the multiple interacting influences and changes over time outlined in this chapter, such research will require new ways of conceptualizing childhood disorders; greater collaboration across disciplines; and the use of novel technologies, sophisticated designs, and complex statistical tools. Considerable advances have been made in all of these areas since earlier editions of this book appeared. The chapters in the present volume provide a state-of-the-art review and critique of current definitions, theories, and research for a wide range of childhood disorders. They also identify current needs and forecast likely future directions for research into child psychopathology.

ACKNOWLEDGMENTS

During the preparation of this chapter, Elizabeth P. Hayden was supported by a grant from the Canadian Institutes of Health Research. We gratefully acknowledge the contribution of David Dozois to previous versions of this chapter. Jasmine Desjardins's assistance in preparing the References section is also acknowledged and appreciated.

NOTES

1. As a matter of convenience, we use the terms "children" and "child" in this chapter and volume to refer to children of all ages, from infancy through adolescence. The diversity within this wide age range will necessitate the use of more specific designations of age and developmental level as appropriate to each discussion. We use the terms "child psychopathology" and "developmental psychopathology" interchangeably in this chapter and in this volume. Other terms that have been used to describe problems during childhood are "abnormal child psychology," "childhood disorders," "atypical child development," "childhood behavior disorders," "childhood emotional and behavioral problems," and "exceptional child development." These differences in terminology reflect the many disciplines and theoretical perspectives that are concerned with understanding and helping disturbed children.

2. We recognize that theory and research in child psychopathology need to be put to the test in the applied arena. However, in this volume we do not consider in any detail the range of assessment, treatment, or prevention strategies available for the problems under discussion. Our decision not to address assessment, treatment, and prevention in this volume was based on two factors. First, we perceived a need for a

substantive review of what we currently know about childhood disorders. Many current treatments for childhood disorders are relatively untested (Kazdin, 2000; Mash & Barkley, 2006), and it was felt that future efforts to test treatment approaches would benefit from a detailed discussion of our current knowledge base for child psychopathology. Second, we wished not to dilute the discussion of theory and research in child psychopathology by attempting to provide cursory coverage of assessment and intervention. Instead, we refer the reader to companion volumes to this one, which have as their primary focus child assessment (Mash & Barkley, 2007) and child treatment (Mash & Barkley, 2006), respectively.

3. A complete discussion of the scope and complexity of issues surrounding the concept of harmful dysfunction is beyond the scope of this chapter. The reader is referred to papers in the *Journal of Abnormal Psychology* (see Clark, 1999, for an overview) and in *Behaviour Research and Therapy* (Houts, 2001; McNally, 2001; Wakefield, 1999a, 1999b, 2001) for excellent discussions of these and related issues.

4. ICD-10 is currently under revision, and ICD-11 is expected to appear in 2015. For information about ICD-11, see its website (*www.who.int/classifications/icd/revision/icd-11faq/en*).

PART II

ADHD, CONDUCT DISORDERS, AND SUBSTANCE USE DISORDERS

CHAPTER 2

Attention-Deficit/Hyperactivity Disorder

JOEL T. NIGG
RUSSELL A. BARKLEY

OVERVIEW

Inattention and impulsivity can occur in a wide range of psychopathologies. For example, substance use, gambling, and antisocial behavior are all associated with impulsivity even in adults. Anxiety or depression can make someone have trouble concentrating at any age. Furthermore, it is normal for little children to be active, energetic, impulsive (acting without thinking of the consequences), and frequently inattentive (not concentrating or having their mind wander on to whatever is nearby). Even in adulthood, most people have trouble concentrating if they are overloaded with too many things to do or a lot of pressure to hurry—a common complaint for people today. Finally, spontaneity and creativity are actually healthy, even though they may often bring impulsivity or off-topic thinking in their wake.

Yet for some individuals their activity level, difficulty controlling impulses (actions or emotional/verbal expression), or inattention are so extreme that they cannot keep up in society. Children with attention-deficit/hyperactivity disorder (ADHD) are so active or impulsive that they cannot sit still, are constantly fidgeting, talk when they should be listening, interrupt people all the time, can't stay on task, don't seem to be listening to others, and constantly lose things. They may often accidentally injure themselves, may be unable to stay seated in the classroom, or may be so inattentive that they cannot learn. They are no longer simply spontaneous by design, but are now out of control in their spontaneity, unable to rein themselves in on a consistent basis. Indeed, these children may be so emotionally volatile or poorly controlled that they are difficult to parent or teach. When they reach adulthood, many continue to have difficulties: They are unable to get work done, get into frequent traffic accidents, or aggravate others in conversations by being off topic or intruding at the wrong time. When things get this bad, individuals are no longer simply expressing the *joie de vivre* of typical children or of outgoing and optimistic adults. They are highly likely to be impaired in social, cognitive, academic, familial, and eventually occupational domains. These impairments can be extensive, and we detail them later. Figure 2.1 depicts our general framework for ADHD; it shows why we consider ADHD extremely important in regard to being a developmental gateway, emanating from multiple early risk factors, and setting the stage for a range of poor life outcomes.

As this volume goes to press, it has been nearly 240 years since Melchior Adam Weikard in 1775 (see Barkley & Peters, 2012) first described disorders of attention in the medical literature. His work was followed a generation later by Alexander Crichton's more elaborate

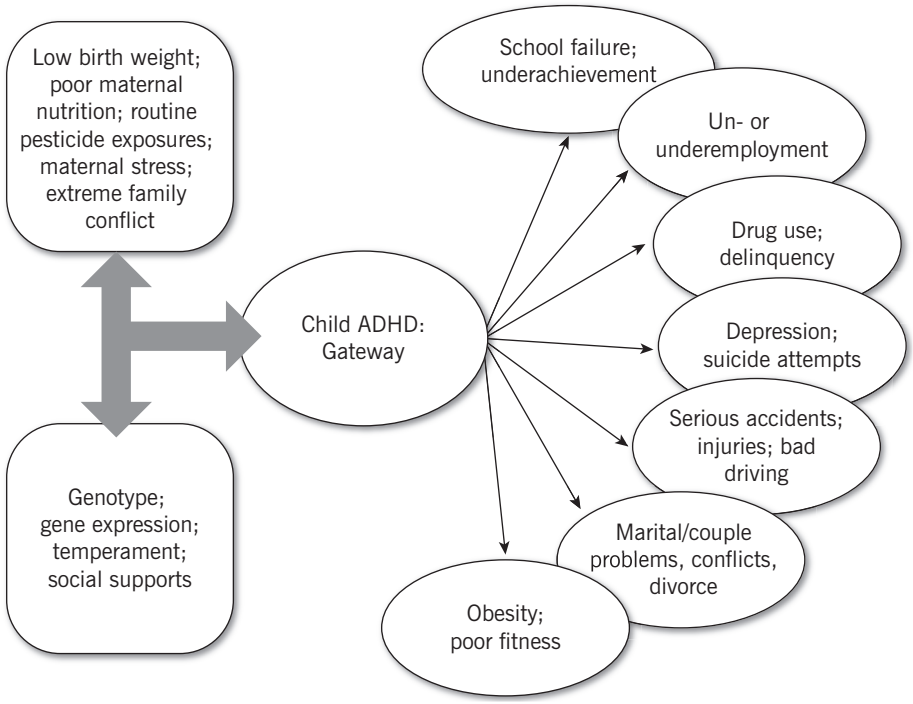

FIGURE 2.1. ADHD as a risk gateway: It likely stems in most instances from multiple prenatal and early developmental risk factors, and it amplifies risk for a wide range of outcomes related to cascading effects of poor self-control throughout life.

descriptions in his medical textbook in 1798 (see Palmer & Finger, 2001). It has also been just over 200 years since Benjamin Rush (1812/1962) provided the first American medical description of extremely impulsive children similar to today's children with ADHD; just over 75 years since the discovery that amphetamine-like drugs could help them (Bradley, 1937); just over 45 years since the first official diagnostic criteria for hyperkinetic reaction of childhood were formulated by the American Psychiatric Association (APA) in the second edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II; APA, 1968); and nearly 35 years since the first formal diagnostic criteria for attention deficit disorder were promulgated in DSM-III (APA, 1980), both officially revising and narrowing the older construct of minimal brain dysfunction (Taylor, 2011). The current volume's publication comes just after the publication of DSM-5 (APA, 2013), marking the latest update in diagnostic criteria and accompanying advisory and descriptive text for mental disorders in psychiatry. The 11th revision of the *International Classification of Diseases* (ICD-11) by the World Health Organization (see *www.who.int/classifications/icd/revision/icd11faq/en*) is expected to follow in 2015 and to have some continued differences from DSM-5. The primary difference historically has been that the ICD definition has been narrower (i.e., has identified fewer children) than the DSM definition. We focus here on the DSM-5 formulation.

As the preceding history indicates, diagnostic labels for these children (and now adults) and the corresponding conceptions of what is wrong with them have changed several times in the past 200-plus years, even as the literature has progressed from rare to extensive scrutiny of this syndrome. Even so, the clinical descriptions have remained remarkably consistent in their essential features over the past century and longer. This constellation of behavior problems may constitute one

of the most well-studied childhood disorders of our time. Nevertheless, these children remain an enigma: Many laypeople are still struggling to accept the notion that the disorder may be a biologically rooted developmental disability or the result of a subtle brain injury, when nothing seems physically wrong.

It is striking that in DSM-5, ADHD is classified as a neurodevelopmental disorder—alongside autism spectrum disorder, specific learning disorder, communication disorders, and intellectual disabilities. This grouping has come about not only because ADHD shares with these other conditions an early onset and persistent course. Like these other conditions, ADHD is often accompanied by other delays and has been associated with enduring alterations in neural development; it also often co-occurs or overlaps with other subtle problems in language, motor, and social development.

This chapter provides an overview of the nature of this disorder; summarizes key aspects of its colorful history in Western society; and describes its diagnostic criteria, its developmental course and outcomes, and what is known about its causes. Along the way, we note key issues that a critical professional needs to bear in mind, and we make some guesses about what the future may hold for this disorder. As will become evident, despite the disorder's current label, the central difficulty is more complex than simply a problem in attention.

HISTORICAL CONTEXT

It is interesting to speculate as to whether ADHD is actually a psychiatric condition of relatively recent historical onset that may have been very rare in ancient times (like anorexia nervosa), or a disorder that seems to have affected our species for several thousand years (like schizophrenia). If we could fill in this gap in historical knowledge, it would put useful constraints on theories of what causes ADHD. There is no obvious description that we know of in the ancient literature, despite the distinct personality types described by Galen. Literary references to individuals having serious problems with inattention, hyperactivity, and poor impulse control can be found in Shakespeare, who alluded to a malady of attention in *King Henry VIII*. As we have noted above, the modern history of ADHD-like medical desciptions can be traced back over 200 years; this early history has been expertly detailed by Taylor (2011) but should be supplemented by more recent discoveries in that history, as discussed below. Here we draw upon his work and more recent articles with a few additional highlights.

As we have noted earlier, the first description of disorders of attention now appears to be the one in a medical textbook by Melchior Adam Weikart in German in 1775 (or even 1770; see Barkley & Peters, 2012). Weikart described adults and children who were inattentive, distractible, impersistent, overactive, and impulsive—characteristics appearing similar to today's description of ADHD. Weikart's account was followed by descriptions of ADHD-like symptoms in a textbook by the Scottish physician Alexander Crichton (Crichton, 1798; see Palmer & Finger, 2001), who may well have studied with Weikart in his medical training. Crichton described patients with "extreme mental restlessness." Next, the famous American physician Benjamin Rush (1812/1962) mentioned a syndrome involving inability to focus attention. In the mid-1800s, German pediatrician Heinrich Hoffman published a book for children, *Der Struwwelpeter* (Hoffman, 1865), which described both a very impulsive, fidgety child he called "Fidgety Phil" and a very inattentive child he called "Johnny Head-in-Air" (see Stewart, 1970); both are recognizable to contemporary clinicians. William James (1890/1950), in *The Principles of Psychology*, described a normal variant of character that he called the "explosive will," which may resemble the difficulties experienced by those who today are described as having ADHD.

As noted by Bader and Hidjikhani (2013), in France the concept of ADHD may have originated in the notion of "mental instability" introduced in the late 19th century under the leadership of Désiré Magloire Bourneville (1885 or 1886, 1895) at the Hospital Bicêtre in Paris. Bourneville observed children and adolescents who had been labeled "abnormal" and placed in medical and educational institutions. Charles Baker, a student of Bourneville, made the first clinical description of hyperactive and impulsive symptoms in four children in his 1892 thesis, according to Bourneville (1895); attention problems were also mentioned in one case in this work. In Great Britain, serious clinical interest in children with ADHD was generated by the physician George Still (1902) in three lectures before the Royal Academy of Physicians. Still described a cohort of 20 children in his clinical practice whom he defined as having a deficit in "volitional inhibition" (p. 1008), which led to a "defect in moral control" (p. 1009) over their own behavior. By 1908, the term "minimal brain damage" had entered the medical lexicon (Taylor,

2011) to represent a group of substantial ADHD-like behavioral disturbances in children who showed no evidence of gross brain damage. In Spain, the physician Rodriguez-Lafora (1917) wrote about his interests in childhood mental illness and described a group of children having psychopathic constitutions, a subset of whom he called the "unstables." His description of them was a close match for the modern view of ADHD (Bauermeister & Barkley, 2010), including inconstancy of attention, excessive activity, and impulsive behavior, as well as the observation that these children frequently got carried away by their adventurous temperaments.

After the great encephalitis epidemics of 1915–1920, it was observed that some children who survived these brain infections had many behavioral problems with defiance, impulsivity, and overactivity; these descriptions do not perfectly match the current conceptualization of ADHD, but have notable similarities (Ebaugh, 1923; Hohman, 1922; Stryker, 1925). These cases and others known to have arisen from birth trauma, head injury, toxin exposure, and infections (see Barkley, 2006) eventually cemented the idea of a "brain-injured child syndrome" (Strauss & Lehtinen, 1947), often associated with intellectual disability. This label would eventually be applied to children manifesting these same behavioral features, but without evidence of brain damage or retardation (Dolphin & Cruickshank, 1951; Strauss & Kephardt, 1955). This concept evolved into "minimal brain damage" and eventually "minimal brain dysfunction" (MBD), as challenges were raised to the original label because of the dearth of evidence for obvious brain injury in most cases (see Kessler, 1980, for a more detailed history of MBD).

In a serendipitous step forward, Bradley (1937) discovered that children with hyperactive behavior and other attributes of MBD showed remarkable improvement in response to stimulant medication (Benzedrine). Although physicians did not begin regularly prescribing stimulants for MBD until the 1950s and 1960s, Bradley's discovery probably also affected conceptions of the disorder, and shifted interest away from cognitive and learning problems toward hyperactivity.

Psychiatric classifications did not formally enter the medical lexicon until after World War II, and the first formal definition of what is now ADHD did not appear until 1980, but the stage was set now for the gradual emergence of the modern conception. By the late 1950s, labels such as as "hyperkinetic impulse disorder" or "hyperactive child syndrome" (Burks, 1960; Chess, 1960) were also in use. The disorder was thought to arise from cortical overstimulation, due to poor thalamic filtering of stimuli entering the brain (Knobel, Wolman, & Mason, 1959; Laufer, Denhoff, & Solomons, 1957). Despite a continuing belief among many clinicians and researchers of this era that the condition had some sort of neurological origin, the influence of psychoanalytic thought and psychosocial theories was also prominent. When DSM-II (APA, 1968) appeared, childhood disorders were noted for the first time. All childhood disorders were described as "reactions," to emphasize their believed exogenous causation, and the hyperactive child syndrome became "hyperkinetic reaction of childhood."

The view that the disorder was not caused by brain damage seemed to follow an argument made somewhat earlier by the prominent child psychiatrist Stella Chess (1960). It set off a major rift between professionals in North America and those in Europe. Even today, there continue to be divergent traditions of how to understand and treat ADHD in the United States and in Europe: European practice guidelines tend to favor psychological intervention as the first line of treatment and medication as the second line, while American practice guidelines tend to reverse this order. Moreover, professionals in Europe continued to view hyperkinesis for most of the latter half of the 20th century as a relatively rare condition of extreme overactivity, and revisions of the ICD have continued to refer to the syndrome as "hyperkinetic disorder." Historically, in North America, Canada, and Australia, such children were diagnosed with ADHD (a developmental disorder), whereas in Europe for much of the late 1900s they were viewed as having a conduct problem or disorder (a behavioral disturbance believed to arise largely out of family dysfunction and social disadvantage). The fundamental tension between viewing these children as having either a neurobiological or a behavioral/psychosocial problem is apparent in arguments about ADHD to varying extents to the present day. Interestingly, the tension can to some extent be resolved conceptually by acknowledging recent findings that ADHD and conduct disorder do indeed have relatively different configurations of genetic and environmental influences. For example, shared environment plays a larger role in conduct problems and aggression than it does in the etiology of ADHD (Burt, 2009). However, for the clinician, whether to prioritize the ADHD or the conduct problems when they co-occur is a difficult choice on which the traditions still tend to differ. We return to this in our integrative remarks later.

By the 1970s, inspired by progress in cognitive and experimental psychology in operationally defining attention, research emphasized the problems with

sustained attention and impulse control in addition to hyperactivity (Douglas, 1972). Douglas (1980, 1983) theorized that MBD involved major deficits in (1) the investment, organization, and maintenance of attention and effort; (2) the ability to inhibit impulsive behavior; and (3) the ability to modulate arousal levels to meet situational demands. Together with these tdeficits went an unusually strong inclination to seek immediate reinforcement. Douglas's emphasis on attention, along with the numerous studies of attention, impulsiveness, and other cognitive sequelae that followed (for reviews, see Douglas, 1983; Douglas & Peters, 1978), may have eventually led to renaming the disorder "attention deficit disorder" (ADD) in DSM-III (APA, 1980). At that time, the syndrome was redefined in narrower terms than those previously used for MBD, and the term MBD was abandoned.

Also notable in DSM-III was that clinical recognition was also given to children who were inattentive, but not necessarily hyperactive. Thus DSM-III specified criteria for two subtypes of ADD: "with hyperactivity" and "without hyperactivity" (although criteria for this second subtype were not proposed). Little research existed at the time that would have supported such a distinction, but the suggestion stimulated research on possible differences between groups of children with ADD. We return to this question about inattentive children and subtypes below.

Even so, concern arose within a few years of the ADD label's creation that the important features of hyperactivity and impulse control were being deemphasized, when in fact they were critically important to differentiating the disorder from other conditions and to predicting later developmental risks (Barkley, 2006; Weiss & Hechtman, 1993). Furthermore, the newly applied technique of computerized factor analysis suggested that the three symptom groups as proposed in DSM-III (inattention, hyperactivity, and impulsivity) were not statistically valid. Therefore, the disorder was renamed "attention-deficit hyperactivity disorder" in DSM-III-R (APA, 1987), and a single list of items incorporating all three symptoms was specified. The condition of ADD without hyperactivity was retained and renamed "undifferentiated ADD"—but it was relegated to an appendix of the manual, away from the main diagnostic section on ADHD, and was still presented without defining operational criteria. The reason given was that insufficient research existed to guide the construction of diagnostic criteria for it at that time.

During the 1980s, reports focused instead on problems with motivation generally, and on an insensitivity to response consequences specifically (Barkley, 1989b; Glow & Glow, 1979; Haenlein & Caul, 1987). Research was demonstrating that under conditions of continuous reward, the performances of children with ADHD were often indistinguishable from those of typical children on various lab tasks, but that when reinforcement patterns shifted to partial and hence delayed reward or to extinction (no-reward) conditions, the children with ADHD showed significant declines in their performance relative to control children (Douglas & Parry, 1983, 1994; Parry & Douglas, 1983). It was also observed that deficits in the control of behavior by rules characterized these children (Barkley, 1989b).

Beginning in the late 1980s, researchers employed information-processing paradigms to study ADHD, and found that problems in perception and information processing were not as evident as were problems with motivation and response inhibition (Barkley, Grodzinsky, & DuPaul, 1992; Schachar & Logan, 1990; Sergeant, 1988; Sergeant & Scholten, 1985a, 1985b). The problems with hyperactivity and impulsivity were also believed to form a single dimension of behavior for all practical purposes (Achenbach & Edelbrock, 1983; Goyette, Conners, & Ulrich, 1978; Lahey et al., 1988), which others described as "disinhibition" (Barkley, 1994, 1997a, 1997b). All of this led to further work on item sets and factor analyses. The result was that when DSM-IV was published (APA, 1994), ADHD was once again described as reflecting two distinct yet correlated dimensions or domains of behavior: One set of symptoms was provided for inattention, and another set of symptoms for hyperactive–impulsive behavior.[1] Unlike DSM-III-R, DSM-IV thus once again permitted the full-fledged diagnosis of a subtype of ADHD that consisted principally of problems with attention (ADHD, predominantly inattentive type), and for the first time provided specific diagnostic criteria for this group—although the conceptual definition was somewhat different from that in DSM-III (because DSM-III had allowed these children to be impulsive but not hyperactive). DSM-IV also permitted, for the first time, the distinction of a subtype of ADHD that consisted chiefly of hyperactive–impulsive behavior without significant inattention (ADHD, predominantly hyperactive–impulsive type). Children having significant problems from both item lists were described as having ADHD, combined type.

Several developments in the literature became notable as the 21st century began. Theoretical conceptions of ADHD continued to broaden in scope. These revisions included interest in more broadly defined at-

tentional features, such as working memory and temporal information processing, that extend well beyond formal definitions of attention and are in part captured by the umbrella term "executive functioning" (Barkley, 1997a; Castellanos, Sonuga-Barke, Milham, & Tannock, 2006). This term often refers to those cognitive abilities involved in goal-directed behavior and problem solving (Barkley, 2013). There was also a revival of interest in dopamine response theories, which focused on reward or reinforcement mechanisms (Sagvolden, Johansen, Aase, & Russell, 2005; Tripp & Wickens, 2008). Particularly notable, in our view, was the growing emphasis on "multiple-pathway models" of ADHD. This perspective suggests that both attention-related theories and motivation-related theories have captured a piece of the truth. Perhaps the inattentive–disorganized symptom domain is best seen as emanating from breakdowns in dorsal prefrontal–striatal neural circuits and executive functioning or cognitive control, whereas the hyperactive–impulsive symptom domain is best seen as related to problems in ventral–prefrontal–limbic neural circuits involved in reward valuation, regulation, and resolution of conflicts in consequences. Alternatively, perhaps different children with ADHD have different reasons for their behaviors: Some may have problems primarily with cognitive control, others primarily with reward response. We take up this idea again later when we consider future directions in the field. (Meantime, for more discussion of these ideas, see Nigg, Hinshaw, & Huang-Pollock, 2006; Nigg, Willcutt, Doyle, & Sonuga-Barke, 2005; Sonuga-Barke, 2005.)

It was not until almost 20 years after DSM-IV appeared that DSM-5 was published (APA, 2013). During this interim period, in addition to developments in theory, technology revolutionized research on child psychopathology. For the first time, ADHD was associated with massive research on structural and functional brain imaging, involving the use of such devices such as magnetic resonance imaging (MRI) in children. That period of time also saw an explosive increase in molecular genetic studies of ADHD. Together, these literatures provided new and tantalizing evidence for biological correlates of ADHD. The authors of DSM-5 thus considered numerous potential improvements to the criteria. Yet, in the end, few substantive changes were made.[2] The same 18 items and the same two behavioral domains (inattention and hyperactivity–impulsivity) are still in force. Indeed, the literature of the last 20 years has provided powerful evidence for the clinical utility and validity of distinguishing these two symptom domains—which, despite being highly correlated, predict different impairments and are likely to have different neural correlates (Willcutt et al., 2012). In particular, symptoms of inattention–disorganization tend to predict such outcomes as academic problems, certain driving difficulties, and peer neglect. Symptoms of hyperactivity–impulsivity tend to predict aggression, peer rejection, and speeding citations, among other difficulties.

Also historically significant has been the further description of a potential second attention disorder, originally believed to be a subtype or at least a subset of ADHD and typically ensconced by clinicians in the DSM-IV category of ADHD, predominantly inattentive type. This condition was first identified in efforts to distinguish DSM-III ADD without hyperactivity from ADD with hyperactivity. It appears that the first description of a subset of children without hyperactivity as being more drowsy, sluggish, and daydreamy appeared in a paper by Lahey, Schaughency, Strauss, and Frame (1984) comparing children in the two ADD groups. Results for studies evaluating such distinctions were mixed (see Milich, Balentine, & Lynam, 2001); yet some investigators repeatedly identified a subset of children having this quite different pattern of inattention and hypoactivity that came to be called by Carlson, Lahey, and Neeper (1986) "sluggish cognitive tempo" (SCT). Its symptoms included staring, daydreaming, drowsiness, mental fogginess/confusion, and slow processing of information, as well as appearing lethargic, hypoactive, and even sleepy. Subsequent studies of children (Barkley, 2013; Bauermeister, Barkley, Bauermeister, Martinez, & McBurnett, 2012) and adults (Barkley, 2012b) led those authors to suggest that SCT is a separate disorder from ADHD, but one that coexists with it in 35–50% of all cases of each. SCT is discussed in more detail later in this chapter.

DESCRIPTION AND DIAGNOSIS

Core Symptoms

As already highlighted, research employing factor analysis has repeatedly identified two distinct yet substantially correlated behavioral dimensions underlying the various behavioral symptoms thought to characterize ADHD (see note 1; also see Burns, Boe, Walsh, Sommers-Flanagan, & Teegarden, 2001; DuPaul, Power, Anastopoulos, & Reid, 1998; Lahey et al., 1994;

Pillow, Pelham, Hoza, Molina, & Stultz, 1998; for a review, see Willcutt et al., 2012). These two dimensions have been identified across various ethnic and cultural groups (Beiser, Dion, & Gotowiec, 2000). They have excellent reliability and discriminant validity (Willcutt et al., 2012), and thus ADHD can be thought of as a syndrome having two distinct but correlated components.

Attention

We have just noted that inattention in DSM is not formally defined relative to the experimental psychology literature. There, attention represents a multidimensional construct (Bate, Mathias, & Crawford, 2001; Mirsky, 1996; Strauss, Thompson, Adams, Redline, & Burant, 2000), and thus several qualitatively distinct problems with attention may be evident in children (Barkley, 2001c). The dimension impaired in ADHD reflects an inability to sustain attention or persist at tasks or play activities, to remember and follow through on rules and instructions, and to resist distractions while doing so. It also seems to involve problems in planning and staying organized, as well as in timeliness and problems in staying alert. One view is that this dimension actually reflects problems in cognitive control, effortful control, or executive function—particularly in working memory—rather than in other types of attention, such as orienting, focusing–executing, or alertness (Barkley, 1997a; Oosterlan, Scheres, & Sergeant, 2005; Seguin, Boulerice, Harden, Tremblay, & Pihl, 1999; Wiers, Gunning, & Sergeant, 1998).

Parents and teachers frequently complain that these children do not seem to listen as well as they should for their age, cannot concentrate, are easily distracted, fail to finish assignments, are forgetful, and change activities more often than others (DuPaul, Power, et al., 1998). Research employing objective measures corroborates these complaints through observations of exhibiting more off-task behavior and less work productivity; looking away more often from assigned tasks (including television); showing less persistence at tedious tasks (such as continuous-performance tasks); being slower and less likely to return to an activity once interrupted; being less attentive to changes in the rules governing a task; and being less capable of shifting attention across tasks flexibly (Borger & van der Meere, 2000; Hoza, Pelham, Waschbusch, Kipp, & Owens, 2001; Lorch et al., 2000; Luk, 1985; Newcorn et al., 2001; Seidman, Biederman, Faraone, Weber, & Ouellette, 1997; Shelton et al., 1998). This inattentive behavior distinguishes these children from those with learning disabilities (Barkley, DuPaul, & McMurray, 1990) or other psychiatric disorders (Chang et al., 1999; Swaab-Barneveld et al., 2000). Although inattentive behaviors are also seen in other conditions, co-occurring conditions do not explain inattention in ADHD (Klorman et al., 1999; Murphy, Barkley, & Bush, 2001; Newcorn et al., 2001; Nigg, 1999; Seidman, Biederman, et al., 1995).

Hyperactive–Impulsive Behavior

Like attention, impulsivity is a multidimensional construct (Nigg, 2000; Olson, Schilling, & Bates, 1999). Several different literatures in psychology have explored the definition of impulsivity in ratings of both personality and behavior, as well as in laboratory paradigms such as speed of responding to cues, delay aversion, and temporal discounting of future rewards. Thus one can think of impulsivity as being related to disinhibition, although there are distinctions to be made between impulsivity and disinhibition as we elaborate along the way.

To understand disinhibition, think of an impulse as a behavior that is "ready to go"—either because a child just did it (e.g., a young child repeats a behavior that just got adults to laugh, even after being told, "That's enough"—the behavior is primed and ready, and now takes effort to stop); because the child is answering quickly on a timed test; because the child has been thinking about it constantly and now has a chance to do it (e.g., the school bell rings and the child is free to leave his or her seat); or because a strong incentive cue has appeared (e.g., the ice cream truck stops in front of the house!).

However, a critical distinction, often lost in the literature, is that stopping an impulse can happen in two fundamental ways—both of which involve attention. The first way is that a child exerts effort or exerts cognitive control (i.e., the child applies attention and thus can voluntarily suppress or possibly inhibit the behavior). Very young children resist a temptation to grab a forbidden toy by looking away form the reward. Older children might be observed deliberately forcing themselves not to talk, for example. You, our readers, can imagine this by introspection: You have an urge to interrupt someone who is saying something wrong, but you force yourself to wait your turn, perhaps because you believe that courtesy is important.

A second way an impulse can be inhibited is due to a stronger impulse. Fear or anxiety can stop a behav-

ior, and, in the process, can capture attention involuntarily. A child who is horsing around in an unsupervised classroom may stop involuntarily—at least for a moment—when there is a loud knock on the door or when a bigger, unfamiliar child enters the room. You can imagine this by introspection when you hesitate to interrupt someone you are afraid to make angry (e.g., your boss, a police officer). Your impulse to avoid the angry response automatically stops you from talking, and now it takes deliberate effort to override the fear if you are going to talk.

But impulsivity can also be thought of as something involving not inhibition, but rather a heightened valuation of reward (Sagvolden et al., 2005). Each child or adult is presumed to give a certain salience or value to a future reward. This salience is influenced by many factors—how far in the future the reward lies, how certain or probable it is, how generally optimistic the individual is about the future, and others. That said, a discounting function can be estimated by comparing, for example, the choice of receiving $100 in a week to receiving $10 today. You might choose $100 in a week instead of $10 right now. However, you would probably choose $10 right now rather than $100 in 5 or 10 years. You have "discounted" the value of that future $100, due to how far away it is in time. This theory of impulsivity states that immediate rewards have unusually high influence relative to later rewards, and furthermore that they shape learning and behavior toward an impulsive style. Neurobiologically, this is thought to be rooted in dopaminergic systems. Cognitively, it can be thought of as a constant process of rapid decision making. In economics, it represents having a high time preference (a preference for consequences near in time). In the past 20 years, as well, there has been renewed interest in the behavioral description of impulsivity. Whiteside and Lynam (2001) have suggested that impulsivity consists of four behavioral components—positive urgency, lack of premeditation, lack of perseverance, and sensation seeking.

DSM-5 does not well capture these different kinds of impulsivity. It does not capture impulsive decision making (valuing of immediate rewards), nor does it very well capture different kinds of disinhibtion. Rather, the symptom items for impulsivity tend to reflect socially intrusive verbal behavior and/or impatience, while ignoring motor, cognitive, and emotional–motivational modalities for impulsive actions. Thus more work needs to be done in future editions of DSM to better capture impulsivity across the lifespan, as now reflected in the scientific literature. Work is also needed to determine which aspects of impulsivity best characterize ADHD and most closely mediate its various outcomes.

Clinically, children with ADHD manifest difficulties with excessive activity level and fidgetiness; less ability to stay seated when required; greater touching of objects; more moving about, running, and climbing than other children exhibit; playing noisily, talking excessively, and acting impulsively; interrupting others' activities; and being less able than others to wait in line or take turns in games (APA, 1994, 2013). Parents and teachers describe them as acting as if driven by a motor, incessantly in motion, always on the go, and unable to wait for events to occur. Research objectively documents them to be more active than other children (Barkley & Cunningham, 1979b; Dane, Schachar, & Tannock, 2000; Luk, 1985; Porrino et al., 1983; Shelton et al., 1998); to have considerable difficulties with stopping an ongoing behavior (Schachar, Tannock, & Logan, 1993; Milich, Hartung, Matrin, & Haigler, 1994; Nigg, 1999, 2001; Oosterlaan, Logan, & Sergeant, 1998); to talk more than others (Barkley, Cunningham, & Karlsson, 1983); to interrupt others' conversations (Malone & Swanson, 1993); to be less able to resist immediate temptations and delay gratification (Anderson, Hinshaw, & Simmel, 1994; Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001; Olson et al., 1999; Rapport, Tucker, DuPaul, Merlo, & Stoner, 1986; Solanto et al., 2001); and to respond too quickly and too often when they are required to wait and watch for events to happen, as is often seen in impulsive errors on continuous-performance tests (Losier, McGrath, & Klein, 1996; Newcorn et al., 2001). Although less frequently examined, similar differences in activity and impulsivity have been found between children with ADHD and those with learning disabilities (Barkley, DuPaul, et al., 1990; Bayliss & Roodenrys, 2000; Klorman et al., 1999; Willcutt et al., 2001). Mounting evidence further shows that these inhibitory deficits are not a function of other psychiatric disorders that may overlap with ADHD (Barkley, Edwards, et al., 2001; Fischer, Barkley, Smallish, & Fletcher, 2005; Halperin, Matier, Bedi, Sharpin, & Newcorn, 1992; Murphy et al., 2001; Nigg, 1999; Oosterlaan et al., 1998; Seidman et al., 1997).

Developmentally, problems with impulsivity (and overactivity) are apparent first (at ages 3–4 years), emerging ahead of those related to inattention (at ages 5–7 years). The symptoms of SCT—a possibly distinct yet related attention disorder, as noted earlier—may

arise even later (ages 8–10) (Hart, Lahey, Loeber, Applegate, & Frick, 1995; Loeber, Green, Lahey, Christ, & Frick, 1992; Milich et al., 2001). Hyperactivity tends to decline normatively with age, and by adolescence hyperactive symptoms in ADHD may be seen in the form of extreme restlessness and a fast tempo, rather than in literally running about the room as in children. Impulsivity probably remains elevated relative to that of peers during development, but in DSM it is closely paired with hyperactivity, so that DSM symptoms of hyperactivity–impulsivity tend to decline normatively with development during childhood and into adolescence. In contrast, inattention and disorganization remain stable during the elementary grades as well as into adolescence (Hart et al., 1995). They eventually decline by adolescence (Fischer, Barkley, Fletcher, & Smallish, 1993b), though not to normative levels.

Why the inattention arises later than the disinhibitory symptoms and does not decline when the latter do over development remains an enigma. A parsiminous explanation may be that societal demands for cognitive control and attention escalate dramatically at ages 5–7 as children enter school. An interesting possibility from a developmental perspective arises from the asynchronous nature of neural development. Limbic and subcortical structures probably play a large role in hyperactivity and impulsivity (Sonuga-Barke, 2005) by driving reward sensitivity. These neural structures mature more rapidly than several cortical areas. In contrast, inattention and executive functioning probably rely on maturation of prefrontal cortices, which are slower to mature than the subcortical areas. Another possibility is that cognitive control and executive functioning rely on interacting long-range neural connections throughout the brain, which also are slow to mature fully (Shaw, Greenstein, et al., 2006).

Situational and Contextual Factors

It is important to recognize that although ADHD is a neurodevelopmental disorder, it is not like more dramatic disorders, such as Down syndrome, that are apparent in all situations. At the risk of reviving the MBD analogy, ADHD may be more analogous to a mild closed head injury, with no apparent physical damage yet subtle decrements in cognition, self-regulation, and other abilities that are noticeable under challenge. Thus, although in some cases of ADHD the syndrome is sufficiently dramatic that it is apparent "at a glance," for the most part the behavioral and cognitive problems seen in ADHD are context-dependent—apparent only in some situations and not all. Douglas (1972) long ago commented on the greater variability of task performances by children with ADHD compared to control children.

Several factors influence the ability of children with ADHD to sustain their attention to task performance, control their impulses to act, regulate their activity level, and/or produce work consistently. The performance of these children is worse (1) later in the day than earlier (Dane et al., 2000; Porrino et al., 1983; Zagar & Bowers, 1983); (2) in more complex tasks, where organizational strategies are required (Douglas, 1983); (3) when restraint is demanded (Barkley & Ullman, 1975; Luk, 1985); (4) under low levels of stimulation (Antrop, Roeyers, Van Oost, & Buysse, 2000; Zentall, 1985); (5) under more variable schedules of immediate consequences in the task (Carlson & Tamm, 2000; Douglas & Parry, 1983, 1994; Slusarek, Velling, Bunk, & Eggers, 2001; Tripp & Alsop, 1999); (6) under longer delay periods prior to reinforcement availability (Solanto et al., 2001; Sonuga-Barke, Taylor, & Heptinstall, 1992; Tripp & Alsop, 2001); and (7) in the absence of adult supervision during task performance (Draeger, Prior, & Sanson, 1986; Gomez & Sanson, 1994).

Besides the aforementioned factors, which chiefly apply to task performance, variability has also been documented across more macroscopic settings. For instance, children with ADHD exhibit more problematic behavior when persistence in work-related tasks is required (chores, homework, etc.) or where behavioral restraint is necessary, especially in settings involving public scrutiny (in church, in restaurants, when a parent is on the phone, etc.) than in free-play situations (Altepeter & Breen, 1992; Barkley, 2012a; Barkley & Edelbrock, 1987; DuPaul & Barkley, 1992). Although they will be more disruptive when their fathers are at home than during free play, children with ADHD are still rated as much less problematic when their fathers are at home than in most other contexts. Fluctuations in the severity of ADHD symptoms have also been documented across a variety of school contexts (Barkley & Edelbrock, 1987; DuPaul & Barkley, 1992). In this case, contexts involving task-directed persistence and behavioral restraint (e.g., the classroom) are the most problematic, with significantly fewer problems in contexts involving less work and behavioral restraint (at lunch, in hallways, at recess, etc.), and even fewer problems during special events (field trips, assemblies) (Altepeter & Breen, 1992).

Associated Developmental Impairments

Children with ADHD often demonstrate deficiencies in many other cognitive and emotional abilities. Among these are difficulties with (1) physical fitness, gross and fine motor coordination, and motor sequencing (Breen, 1989; Denckla & Rudel, 1978; Harvey & Reid, 1997; Kadesjo & Gillberg, 2001; Mariani & Barkley, 1997); (2) speed of color naming (Carte, Nigg, & Hinshaw, 1996); (3) verbal and nonverbal working memory and mental computation (Barkley, 1997b; Mariani & Barkley, 1997; Murphy et al., 2001; Zentall & Smith, 1993); (4) story recall (Lorch et al., 2000; Sanchez, Lorch, Milich, & Welsh, 1999); (5) planning and anticipation (Grodzinsky & Diamond, 1992; Klorman et al., 1999); (6) verbal fluency and confrontational communication (Grodzinsky & Diamond, 1992; Zentall, 1988); (7) effort allocation (Douglas, 1983; Nigg, Hinshaw, Carte, & Treuting, 1998; Sergeant & van der Meere, 1994; Voelker, Carter, Sprague, Gdowski, & Lachar, 1989); (8) developing, applying, and self-monitoring organizational strategies (Clark, Prior, & Kinsella, 2000; Hamlett, Pellegrini, & Connors, 1987; Purvis & Tannock, 1997; Zentall, 1988); (9) internalization of self-directed speech (Berk & Potts, 1991; Copeland, 1979; Winsler, 1998; Winsler, Diaz, Atencio, McCarthy, & Chabay, 2000); (10) adhering to restrictive instructions (Danforth, Barkley, & Stokes, 1991; Roberts, 1990; Routh & Schroeder, 1976); and (11) self-regulation of emotion (Barkley, 2010; Braaten & Rosen, 2000; Hinshaw, Buhrmester, & Heller, 1989; Maedgen & Carlson, 2000).

The last-mentioned difficulties, those with emotional control, may be especially salient in children having ADHD with comorbid oppositional defiant disorder (ODD) (Melnick & Hinshaw, 2000). Several studies have also demonstrated that ADHD may be associated with less mature or diminished moral development (Hinshaw, Herbsman, Melnick, Nigg, & Simmel, 1993; Nucci & Herman, 1982; Simmel & Hinshaw, 1993). Many of these cognitive difficulties appear to be specific to ADHD and are not a function of its commonly comorbid disorders, such as learning disabilities, depression, anxiety, or ODD/conduct disorder (CD) (Barkley, Edwards, et al., 2001; Clark et al., 2000; Klorman et al., 1999; Murphy et al., 2001; Nigg, 1999; Nigg et al., 1998). However, more recent work (Barkley, 2010) has begun to articulate more clearly the problems in emotion regulation that seem to accompany ADHD. Clinically, this means that children with ADHD are more likely to get angry, sad, explosive, or moody than those without ADHD. Formally, this can be measured as reductions in the efficiency of physiological regulation of emotion (Musser et al., 2011).

DIAGNOSTIC CRITERIA AND RELATED ISSUES

The most recent diagnostic criteria for ADHD as defined in DSM-5 (APA, 2013) are set forth in Table 2.1. Like those in DSM-IV, to which these are qute similar, the DSM-5 diagnostic criteria represent the best consensus of experts in the field and were approved after extensive reviews of the literature, data reanalyses, and field trials and several periods of public comment.

Even so, the criteria have not escaped controversy and are not without limitations. As noted earlier, there will continue to be controversy—and, we hope, new research—on the validity and boundaries of a putatively more homogeneous inattentive group; on irritability and emotional dysregulation; on measurement of impulsivity, especially in adulthood; and overall on different ways to capture heterogeneity in ADHD. The subtyping of ADHD in DSM-IV has been essentially carried forward to DSM-5, although the word "presentation" instead of "type" is used for each and they have been classed as modifiers to convey, as explained in the accompanying text to the criteria, that these presentations are quite unstable and that clinicians should not see them as permanent descriptors. The hyperactive–impulsive type from DSM-IV had limited validity beyond preschool age (see Willcutt et al., 2012), and this is likely to remain a concern even for the concept of a presentation rather than a subtype. The DSM-IV field trial found that those diagnosed with predominantly hyperactive–impulsive ADHD were primarily preschool-age children, whereas those with the combined type of ADHD were primarily school-age children. This picture has not changed much in the ensuing two decades, and the major review by Willcutt and colleagues (2012) has raised significant questions about the validity of this category after preschool.

The issue of developmental appropriateness of the criteria will continue to be a concern as well. The DSM-IV field trials, which remain the main basis for the criteria set and cutoff points, were conducted on children ages 4–16 years. Even for DSM-5, a proper field trial of adults was not conducted. Substantial reasons exist to expect a lower symptom threshold to be appropriate in adults, and DSM-5 has appropriately

TABLE 2.1. DSM-5 Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder

A. A persistent pattern of inattention and/or hyperactivity–impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. **Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
   b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
   c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
   d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
   e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
   f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing records, completing forms, reviewing lengthy papers).
   g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
   h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
   i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).

2. **Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fidgets with or taps hands or feet or squirms in seat.
   b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
   c. Often runs about or climbs in situations where it is inappropriate. (**Note:** In adolescents or adults, may be limited to feeling restless).
   d. Often unable to play or engage in leisure activities quietly.
   e. Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
   f. Often talks excessively.
   g. Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).
   h. Often has difficulty waiting his or her turn (e.g., while waiting in line).
   i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).

B. Several inattentive or hyperactive–impulsive symptoms were present prior to age 12 years.

C. Several inattentive or hyperactive–impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).

D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social academic, or occupational functioning.

(continued)

TABLE 2.1. *(continued)*

E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

Specify whether:

314.01 (F90.2) Combined presentation: If both Criterion A1 (inattention) and Criterion A2 (hyperactivity–impulsivity) are met for the past 6 months.

314.00 (F90.0) Predominantly inattentive presentation: If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity–impulsivity) is not met for the past 6 months.

314.01 (F90.1) Predominantly hyperactive/impulsive presentation: If Criterion A2 (hyperactivity–impulsivity) is met and Criterion A1 (inattention) is not met for the past 6 months.

Specify if:

In partial remission: When full criteria were previously met, fewer than the full criteria have been met for the past 6 months, and the symptoms still result in impairment in social, academic, or occupational functioning.

Specify current severity:

Mild: Few, if any, symptoms in excess of those required to make the diagnosis are present, and symptoms result in no more than minor impairments in social or occupational functioning.

Moderate: Symptoms or functional impairment between "mild" and "severe" are present.

Severe: Many symptoms in excess of those required to make the diagnosis, or several symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social or occupational functioning.

provided a lower threshold for adults and older adolescents, but only by one symptom (five symptoms) versus the threshold for children (six symptoms). That work was based on secondary, as yet unpublished analyses of five different data sets. Other research indicates that an even lower cutoff may be most appropriate (perhaps as low as four symptoms; Barkley, Murphy, & Fischer, 2008). Furthermore, revised cutoffs or duration periods for preschoolers under age 4 may be needed. Finally, the validity of the three presentations in adults with the five-symptom cutoff is unknown.

Also as noted earlier, the criteria may not provide adequate coverage of impulsivity, especially for older adolescents and adults. More work will be needed to integrate various emerging measures of impulsivity with the criteria for ADHD in future editions of DSM.

It is important to note the language in the DSM-5 criteria, which is also echoed in the manual's text, about the importance of obtaining corroborating information from other sources besides the patient—particularly to verify cross-situational display of symptoms. This is an improvement over DSM-IV and is a point too easily overlooked in clinical practice. It is important because over- versus underreporting of symptoms is an important issue in this population (Barkley, Knouse, & Murphy, 2011; Edwards, Barkley, Laneri, Fletcher, & Metevia, 2001; Fischer, Barkley, Fletcher, & Smallish, 1993a; Henry, Moffitt, Caspi, Langley, & Silva, 1994; Mannuzza & Gittelman, 1986; Romano, Tremblay, Vitaro, Zoccolillo, & Pagani, 2001).

A different issue pertains to whether or not the criteria should be adjusted for the gender of the children being diagnosed. Research evaluating these and similar item sets demonstrates that male youngsters display more of these items, and do so to a more severe degree, than do female youngsters in the general population (Achenbach, 1991; DuPaul, Power, et al., 1998). Given that the majority of children in the DSM-IV field trial were boys (Lahey et al., 1994), the symptom threshold chosen in the DSM-IV and now carried forward to DSM-5, at least for children, is more appropriate to males. This results in girls' having to meet a higher threshold relative to other girls to be diagnosed as having ADHD than boys must meet relative to other boys. Gender-adjusted thresholds would seem to be in order to address this problem; yet such thresholds would evaporate the currently disproportionate male-to-female ratio of 2.5:1 found across studies (see below)

in children. They would also potentially obscure relevant etiological factors, such as hormonal regulation of neural development in relation to ADHD (Martel, 2013). In contrast, ADHD in adults does not show significant sex differences in the nature of the symptoms or in the ratio of diagnosis in men versus women (Barkley, 2011). Why the sex difference should attenuate by adulthood remains an enigma.

Age and Developmental Considerations

Preschoolers

A key area of controversy has been the diagnosis of ADHD in very young children (ages 2–3 years). The DSM-5 text (APA, 2013) points out that it is difficult to establish a valid diagnosis below age 4, but the criteria do not forbid doing so. Yet it is unclear whether a differentiation of inattention or impulsivity from irritability, defiance, aggression, or immaturity is possible at younger ages. The 6-month requirement for duration of problems is also likely to be problematic in preschoolers. Many children age 3 years (or younger) may have parents or preschool teachers who report concerns about the children's activity level or attention, but these concerns have a high likelihood of remission within 12 months (Beitchman, Wekerle, & Hood, 1987; Campbell, 2006; Lerner, Inui, Trupin, & Douglas, 1985; Palfrey, Levine, Walker, & Sullivan, 1985). It would seem that the 6-month duration specified in the DSM-5 criteria may be too brief for preschoolers, resulting in overidentification of children with ADHD in this age range (false positives). However, this same body of research found that for those children whose problems lasted at least 12 months or beyond age 4 years, the behavior problems were highly persistent and predictive of continuance into the school-age range. Such research suggests that the duration of symptoms be set at 12 months or more at least in preschoolers. This is another issue to be considered for the next edition of DSM.

Adults

As noted above, DSM-5 has lowered the cutoff point for adults from six symptoms to five, on the basis of analysis of five different data sets. A key problem with diagnosis in adults is determining the history. However, much is now known about adolescent and adult outcomes from longitudinal studies. We discuss the adult outcomes further in a subsequent section.

Subtypes

Despite the clear validation of the two-domain structure of ADHD, an ability to distinguish subtypes easily does not follow—and, despite the substantial literature, the picture on subtypes remains ambiguous. This would be expected, given that the two dimensions are highly correlated, sharing at least 50–64%+ of their variance. Several trends were noted in a comprehensive review commissioned to inform the authors of DSM-5 (Willcutt et al., 2012):

1. The DSM-IV subtype designations were not stable over time, at least when the single-reporter interview methods adopted in longitudinal studies were used. Thus a child could be diagnosed as having one subtype in one year and another subtype the next year.

2. The differences between the subtypes were primarily in degree rather than kind. Children with the combined type of ADHD had worse impairments than did children with the inattentive type, while the hyperactive–impulsive type, rare in children after preschool, was little studied.

3. Neurobiological studies (e.g., functional brain imaging or molecular genetics) that directly compared these subtypes were still almost nonexistent. DSM-5 therefore removed their designations as "types" and replaced them with clinical "presentations" that are intended to be seen as course specifiers, although because they still have distinct codes they may in fact simply function in a fashion similar to the DSM-IV subtypes. This was intended to weaken the tendency to reify the unstable types, while also leaving open the possibility for new data that might address biological differences between these presentations.

The Willcutt and colleagues (2012) review also revealed that there has been insufficient empirical study of children who are inattentive but not hyperactive. That is, children who have the DSM-IV inattentive subtype or the DSM-5 inattentive presentation can still be hyperactive—just not hyperactive enough to meet criteria for the combined presentation. Thus some observers believe that if there are indeed distinct subtypes, the DSM formulation may include "subthreshold com-

bined" children along with "true inattentive" children. The idea here is that the cutoff point is in the wrong place.

That claim is intuitively appealing but has been difficult to win, however, for two reasons. First, most studies use the DSM-IV subtypes, thus evading the question of whether the grouping is "wrong" in the first place. Second, regardless of the definitions used (prior to DSM-IV, various definitions were used because DSM-III provided no formal criteria for this group), the data tend to follow a severity pattern. That is, typically the correlates of inattention accrue to the inattentive group and the correlates of inattention and of hyperactivity accrue to the combined group, suggesting that subtypes are little more than arbitrary cutoff points on these behavioral dimensions that can mix in different ways.

Nonetheless, new evidence is emerging. One kind of evidence that children with the DSM inattentive type may include children with the subthreshold combined type came from Stawicki, Nigg, and von Eye (2006), who reviewed family history data. They found that across thousands of families pooled over multiple studies, children with the predominantly inattentive type of ADHD were likely to have relatives with both this type and the combined type, whereas children with the combined type were likely to have relatives with the combined type. DSM, by contrast, still allows up to five hyperactive–impulsive symptoms in children with the "inattentive" presentation. Although validation data remain sparse, initial evidence suggests that these children may indeed have more different, and not just less severe, cognitive problems in some domains than children who are at subthreshold levels for the combined presentation, with four or five symptoms of hyperactivity–impulsivity (Carr, Henderson, & Nigg, 2010; Milich et al., 2001). The presence of inattention only, with low levels of hyperactive–impulsive symptoms, is the condition that earlier investigators identified as SCT—and that later research suggests might even form a separate yet potentially comorbid attention problem, as noted above and discussed further below.

Overall, a key question for the field now requires scrutiny: Is it simply the case that more symptoms lead to more impairment, so that subtypes merely represent differences of degree and not of kind? Or are there true differences in kind, hidden within the current DSM parameters? This will remain a "hot topic" in the years to come, and perhaps the next edition of DSM will therefore have enough literature behind it to justify renewed recognition of purely inattentive, or inattentive–sluggish, children.

It is important to reiterate that in both DSM-IV and DSM-5, "inattention" and "impulsivity" are not formally defined. Indeed, impulsivity as currently understood is not well captured in the DSM-5 criteria, as discussed earlier. DSM-5 (like DSM-IV before it) provides for three impulsivity items that pertain primarily to verbal behavior and social intrusiveness. Current understandings of impulsivity instead emphasize the relative weighting of immediate over later reward during decision making (reminiscent of the ideas about ADHD in the 1980s, also described earlier). This type of behavior, however, is not well represented in DSM. Similarly, inattention in DSM is simply defined by off-task behavior or problems with concentrating. In formal terms, inattention may be due to low energy, poor working memory, problems with controlling sensory or cognitive interference, poor cognitive control, or poor self-regulation—all of which are more precise terms that capture forms or types of attention. Debate about how to assemble these different types of attention into an overall picture of different kinds of children with ADHD continues.

However, it is increasingly believed that ADHD probably reflects multiple underlying breakdowns in cognition and neurobiology. It is also likely that in a group of children with ADHD, not all will have the same neurobiology or the same cognitive dysfunction. A neurobiological subtyping or subgrouping of individuals with ADHD remains the sought-after "holy grail" in this field, as we elaborate subsequently under "Future Directions."

Although DSM-5 has commendably urged consideration of data from multiple informants, a key problem that the authors of DSM-5 have deferred to the future concerns how such information should be combined. Is a symptom present if any reporter endorses it? Should reports from different informants be averaged? Or are some reporters more valid than others for some symptoms at some ages? This degree of nuanced weighting of reporting would be the ideal, especially given the well-established limited agreement across parents and teachers (Achenbach, McConaughy, & Howell, 1987)—and it is increasingly feasible, with the worldwide spread of microcomputing technology such as that found on smart phones. Such disagreements among sources certainly reflect differences in a child's behavior as a function of true differential demands of

these settings. But they also reflect differences in the attitudes and judgments of different people. Clinicians are left to make difficult judgments about the reliability of the different reports and the likelihood of variation across settings in determining whether the appropriate formulation is ADHD, or whether situational problems at home or school may need to be addressed. The best discrimination of children with ADHD from other groups may be achieved by blending the reports of parents and teachers, such that one counts the number of different symptoms endorsed across *both* sources of information (Crystal, Ostrander, Chen, & August, 2001; Mitsis, McKay, Schulz, Newcorn, & Halperin, 2000), as was actually done in the earlier DSM-IV field trial (Lahey et al., 1994).

Many of these problematic issues are likely to be addressed in future editions of DSM. Even so, the present criteria are actually some of the best ever advanced for the disorder; they represent a vast improvement over the state of affairs that existed prior to 1980. The various editions of DSM also have spawned a large amount of research into ADHD—its symptoms, subtypes, criteria, and even etiologies—that probably would not have occurred had such criteria not been set forth for professional consumption and criticism. The most recent criteria provide clinicians with a set of guidelines that are specific, reliable, empirically justifiable, predictive, and based on the scientific literature.

Sluggish Cognitive Tempo

SCT is not recognized in DSM-5, and so there are no officially endorsed criteria for its clinical recognition. Saxbe and Barkley (2013) recently reviewed the literature for clinicians, and much of this discussion is based on their paper. The most salient symptoms of SCT (Barkley, 2012b, 2013; Carlson & Mann, 2002; Garner, Marceaux, Mrug, Patterson, & Hodgens, 2010; McBurnett, Pfiffner, & Frick, 2001; Penny, Waschbusch, Klein, Corkum, & Eskes, 2009) are as follows: A child (1) often daydreams, (2) has trouble staying awake/alert, (3) is mentally foggy/easily confused, (4) stares a lot, (5) is "spacey"/mind is elsewhere, (6) is lethargic, (7) is underactive, (8) is slow-moving/sluggish, (9) doesn't process questions or explanations accurately, (10) has a drowsy/sleepy appearance, (11) is apathetic/withdrawn, (12) is lost in thoughts, (13) is slow to complete tasks, and (14) lacks initiative/has trouble sustaining effort. The last two symptoms, however, are as likely to be associated with ADHD as with SCT in children or adolescents, and so they are not recommended for assisting with differential diagnosis between these two types of attention disorders (Barkley, 2013). But the remaining 12, among others (Penny et al., 2009), appear to be highly useful for making such distinctions.

SCT symptoms cluster into separate symptom dimension(s) from the two traditional yet highly intercorrelated ones of inattention and hyperactivity–impulsivity for ADHD both in children (Jacobson et al., 2012; Penny et al., 2009) and in adults (Barkley, 2011). Two (or more) symptom dimensions are often evident: (1) daydreaming/sleepiness and (2) being slow/sluggish/lethargic (Barkley, 2013; Penny et al., 2009). A third dimension, representing low initiation/persistence, may also be present (Jacobson et al., 2012) but may be as correlated with ADHD inattention symptoms as it is with SCT, thus making it less useful for case discrimination. The factors emerge regardless of approaches to measurement, and in both clinic-referred and community-based cases. Whether researchers have used parent and teacher ratings (Barkley, 2013; Bauermeister et al., 2012; Garner et al., 2010; Hartman, Willcutt, Rhee, & Pennington, 2004; Jacobson et al., 2012; Penny et al., 2009), observations of behavior at school (McConaughy, Ivanova, Antshel, Eiraldi, & Dumenci, 2009), and observations of behavior in clinical settings (McConaughy, Ivanova, Antshel, & Eiraldi, 2009), SCT symptoms are shown to be distinct from ADHD ones. This is true in adult self-reports as well (Barkley, 2012b). SCT symptoms are significantly but moderately correlated with the ADHD symptom dimensions, and particularly with the inattention dimension of ADHD; share approximately 10–25%+ of their variance. Yet SCT symptoms are substantially less correlated with ADHD symptoms than the two ADHD symptom dimensions are to each other (Barkley, 2012b, 2013; Penny et al., 2009). And SCT symptoms demonstrate a far lower relationship to hyperactive–impulsive symptoms than they do to inattention symptoms (Barkley, 2012b, 2013; Garner et al., 2010; Hartman et al., 2004; Jacobson et al., 2012; Penny et al., 2009; Wahlstedt & Bohlin, 2010). SCT symptoms are thus as independent of or partially coupled to ADHD symptoms as other symptom dimensions of child and adult psychopathology are to each other.

Unlike ADHD, SCT does not seem to be as serious and pervasive a disorder of executive functioning as ADHD is, whether tests of executive functioning

(Bauermeister et al., 2012; Wahlsted & Bohlin. 2010) or rating scales of such functioning in daily life (Barkley, 2012b, 2013) are used. Indeed, SCT may not be a disorder of executive functioning at all (Barkley, 2013).

SCT can overlap with ADHD. In the study of U.S. children by Barkley (2013), more than half (59%) of those participants qualifying for a designation of SCT also qualified as having ADHD. Where overlap existed, it was principally with those DSM-IV ADHD subtypes having significant inattention symptoms rather than with the hyperactive–impulsive subtype; this finding is consistent with earlier studies exploring this overlap in children (Garner et al., 2010; Penny et al., 2009; Skirbekk, Hansen, Oerbeck, & Kristensen, 2011) and adults (Barkley, 2012b). 39% of the children qualifying for ADHD of any type also qualified for SCT. Again, these findings agree with prior studies of children (Garner et al., 2010; Hartman et al., 2004) and adults (Barkley, 2012b). For instance, a recent survey of U.S. adults relying on self-report (Barkley, 2012b) found that 5.8% of the sample met criteria for high SCT symptoms. Approximately half (54%) of those participants qualifying for SCT also qualified for ADHD, based on their self-reported symptoms. About half of the individuals qualifying for ADHD of any type (46%) also qualified for SCT. The relationship of SCT to ADHD appears to be one of comorbidity between two relatively distinct but related or partially coupled disorders, such as anxiety and depression, and not one of subtyping within a single shared disorder.

The SCT dimension relates more closely to internalizing symptoms than do ADHD symptoms (Bauermeister et al., 2012; Becker & Langberg, 2012; Capdevila-Brophy et al., in press; Carlson & Mann, 2002; Garner et al., 2010; Hartman et al., 2004; Penny et al., 2009). This remains the case even after controlling for the contribution of ADHD symptoms (Bauermeister et al., 2012; Becker & Langberg, 2012; Penny et al., 2009). There is also a weaker association of SCT with externalizing symptoms or disorders, such as ODD, CD, or psychopathy, in children. ADHD, in contrast, is routinely linked to a higher risk for comorbidity with the externalizing symptom dimension generally, and specifically with ODD and CD, as discussed above.

Salient differences exist between SCT and ADHD in ratings of impairment in daily life activities (Barkley, 2012b, 2013). Space precludes a detailed discussion of these findings. Evidence shows that SCT is more associated with social withdrawal and peer neglect or oversight, whereas ADHD is associated with significant peer conflicts, aggression, bullying/victimization and rejection (Milich et al., 2001; Penny et al., 2009). Both disorders impair academic performance, but ADHD is far more closely associated with disruptive behavior in school and with greater impairment in domains outside school that require restraint and self-regulation, such as following rules, doing chores or homework, or driving. SCT, in contrast, is as impairing (if not more so) in educational work performance and occupational functioning as is ADHD, but it is less disruptive of driving.

In closing this discussion, it is worth noting that SCT may not be the best term for this disorder, as noted by Saxbe and Barkley (2013). First of all, it implies an understanding of the underlying neuropsychological deficits in SCT that actually remains unknown. Second, it carries some similar pejorative connotations to those that may be conveyed by the phrases "slow learner" or "having low intelligence," which is hardly the case. We would endorse such labels as "concentration deficit disorder," "developmental concentration disorder," or "focused attention disorder" as more generally and socially acceptable. They retain the emphasis on a problem with attention or arousal/alertness—a problem that is likely to be distinct from ADHD—but without any implication of underlying cognitive processes or denigration.

THEORETICAL CONSIDERATIONS

Theories of ADHD's core pathophysiology can be understood from both a psychological perspective and a neurobiological perspective. From a psychological perspective, many theories of ADHD have been proposed over the past century to account for the diversity of findings so evident in this disorder (for a more detailed review, see Barkley, 1999). However, within the psychological perspective they fall into two major groups of theories, depending on whether they emphasize some form of cognitive control ("top-down" theories) or emphasize motivational or energetic factors ("bottom-up" theories); recent theories combine these views. These different theories vary in their degree of comprehensiveness or the extent to which they are really a theory versus a hypothesis. Here, we note several of the key proposals. Table 2.2 lists the major modern theories of psychological mechanism, to make it easier to track them during this discussion.

Some of these theories have been discussed above (see "Historical Context"). Early top-down theories

TABLE 2.2. Examples of Modern Theories of Psychological Dysfunction in ADHD

Year	Author	Core concept	Type of theory
1972	Douglas	Attention	Top-down
1981	Barkley	Rule-governed behavior	Top-down
1997	Barkley	Response inhibition	Top-down
1972	Sagvolden	Reinforcement gradient	Bottom-up
1987	Haenlein & Caul	Reward response	Bottom-up
1997	Quay	Behavioral inhibition	Bottom-up
1988	Sergeant	Arousal/activation	Bottom-up
1992	Sonuga-Barke	Delay aversion	Bottom-up
1993	Schachar	Response inhibition	Top-down
2002	Castellanos & Tannock	Temporal processing and control	Hybrid
2005	Sagvolden	Reinforcement gradient/dopamine	Bottom-up
2005	Sonuga-Barke	Dorsal–ventral dual process	Hybrid
2005	Nigg & Casey	Cognitive and emotional processing	Hybrid

were Still's (1902) notion of defective volitional inhibition and moral regulation of behavior; Douglas's (1972, 1983) theory of deficient attention, inhibition, arousal, and preference for immediate reward; and Barkley's (1981, 1989b) idea of a deficit in rule-governed behavior. Classic or early bottom-up theories were ADHD as a deficit in sensitivity to reinforcement (Haenlein & Caul, 1987) or as involving a steep reward-discounting gradient (see Sagvolden et al., 2005, for a summary of the conclusions of their two decades of work on this idea). Quay (1997), relying on Gray's (1982) neuropsychological model of anxiety, proposed that ADHD arises from a deficit in the brain's behavioral inhibition system (what Nigg, 2000, called "motivational inhibition"). An influential integrative model designed to better locate the ADHD problem was provided by Sergeant (1988). According to this model, behavioral control arises from a specific interplay of "energetic factors" such as arousal (readiness to perceive a signal), activation (readiness to respond), and effort (motivation) with "executive functioning" (i.e., what today would be called "cognitive control"). Sergeant reviewed evidence that ADHD might be most particularly associated with problems in activation or arousal.

Meantime, relying on Logan's "race" model of inhibition, Schachar and colleagues (1993) refined the top-down theories by arguing for a central deficit in inhibitory processes in those with ADHD, but using a perspective we would call "top-down or controlled inhibition" (executive inhibition). In this model, an event or stimulus is hypothesized to trigger both an activating or primary response and an inhibitory response, creating a competition or race between the two as to which will be executed first. Disinhibited individuals, such as those with ADHD, are viewed as having slower initiation of inhibitory processes than typical children do. An extensive literature confirms that this is so, but does not resolve the degree to which this accounts for other symptoms of ADHD.

Refined and sophisticated versions of bottom-up motivational or reinforcement gradient theories have continued to emerge, driven by an improved neuroscience-based understanding of how dopamine signaling influences regulation. The most comprehensive articulation of this perspective has been provided by Sagvolden and colleagues (2005), who developed their model using an animal strain called the "spontaneously hypertensive" rat. These animals had a steeper discounting of future reinforcers than comparison strains. The application to ADHD relies on a detailed understanding of how reinforcement × delay gradients change the likelihood of impulsive behavior in different contexts. The most important point for our purposes is that the theory posits a specific failure of dopamine activity as driving the development over time of a hyperactive–impulsive style via countless repetitions of steep-gradient response contingency experiences. A nuanced alternative to this theory came from Tripp and Wickens (2008), who posited an abnormal dopamine response not for future reinforcers, but for present reinforcers.

A related conception has been offered by Sonuga-Barke (2005; Sonuga-Barke et al., 1992), who uses the term "delay aversion." In this variation of the theory, a need for stimulation makes absence of feedback (or absence of reinforcement of any kind) unusually unpleas-

ant for individuals with ADHD, leading them to take action to drive a response from the environment. This action, by provoking environmental or social response, would create the possibility of reward. However, most of the evidence related to that theory relies on findings of a steep reinforcement-learning or impulsive-choice reward gradient, thus overlapping with evidence for the reinforcement gradient theory.

The most comprehensive articulation of a top-down model has come from Barkley (1994, 1997a, 1997b, 2001b, 2001a, 2012c). He has outlined a theory of ADHD that attempts to integrate numerous observations into a more comprehensive theory, initially anchored on the well-established aspect of poor inhibition of prepotent responses. Figure 2.2 illustrates the original theory (Barkley, 1997a).

This theory proposes that self-regulation requires the ability to inhibit a behavioral response, and that four other executive functions are dependent upon this for their own effective execution. These four executive functions provide for self-regulation, bringing behavior progressively more under the control of time and the influence of future over immediate consequences. The interaction of these executive functions permits far more effective adaptive functioning oriented toward the social future (social self-sufficiency). In this model, problems with arousal regulation and reward discounting are "downstream" from a fundamental problem in behavioral inhibition. Like other theories, this theory is more relevant to the combined type/presentation of ADHD than to the purely inattentive type/presentation or SCT.

The five executive functions are believed to develop via a common process. All represent private, covert forms of behavior that at one time in early child development (and in human evolution) were entirely publicly observable and were directed toward others and the external world at large. With maturation, this outer-directed behavior becomes turned on the self as a means to control one's own behavior. Such self-directed behaving then becomes increasingly less observable to others as the suppression of the public, peripheral, musculoskeletal aspects of the behavior progresses. The child is increasingly able to act toward the self without publicly displaying the actual behavior being activated. This progressively greater capacity to suppress the publicly observable aspects of behavior is what is meant here by the terms "covert," "privatized," or "internalized." The child comes to be capable of behaving internally (in the brain) without showing that response through the peripheral muscles, at least not to the extent that it is visible to others. As discussed elsewhere (Barkley, 1997a, 2001a), this behavior-to-the-self can still be detected in very subtle, vestigial forms as slight shifts in muscle potential at those peripheral sites involving the muscles used in performing the public form of that behavior (e.g., when one engages in verbal thought, one still slightly moves the lips, tongue, larynx, etc.). In this sense, all of the executive functions follow the same general sequence as the internalization of speech (Diaz & Berk, 1992; Vygotsky, 1967/1987, 1978), which in this model forms the third executive function.

This theory has had several salutary effects, including stimulating a wealth of new research on executive functioning, better articulating the operational definition of an "executive function" (a form of self-directed behavior or self-regulation), identifying the kinds of executive functioning relevant to ADHD, and spurring theoretical perspectives to be more precise in explaining ADHD. More recently, Barkley has conceded that the central deficit in ADHD may be a deficiency not only in behavioral inhibition as initially proposed, but in metacognition (self-awareness and working memory) which was initially believed to be deficient secondary to the inhibition deficit (Barkley, 1997b). In the latest iteration of this theory (Barkley, 2012c), self-awareness (self-directed attention) has been added to this model as a foundational executive function developing alongside inhibition (self-restraint). These executive functions precede and eventually coexist with the others across development: nonverbal and verbal working memory (self-imagery and self-speech), emotional and motivational self-regulation, and planning/problem solving (private self-directed play).

Also in this recent version, Barkley views executive functioning as an inherently social neuropsychological adaptation, having evolved to address problems that have arisen in human group living social existence. He has borrowed the concept of an "extended phenotype" from evolutionary biology to explain how these executive functions can produce effects at considerable spatial, temporal, and social distances to form four levels of executive functioning in daily life. These levels are (1) instrumental/self-directed, comprising the executive functions just discussed; (2) adaptive/self-reliant, in which instrumental executive functions subserve the development of self-care, independence from others, and social self-defense; (3) tactical/reciprocal, in which the lower-level executive functions now contribute to

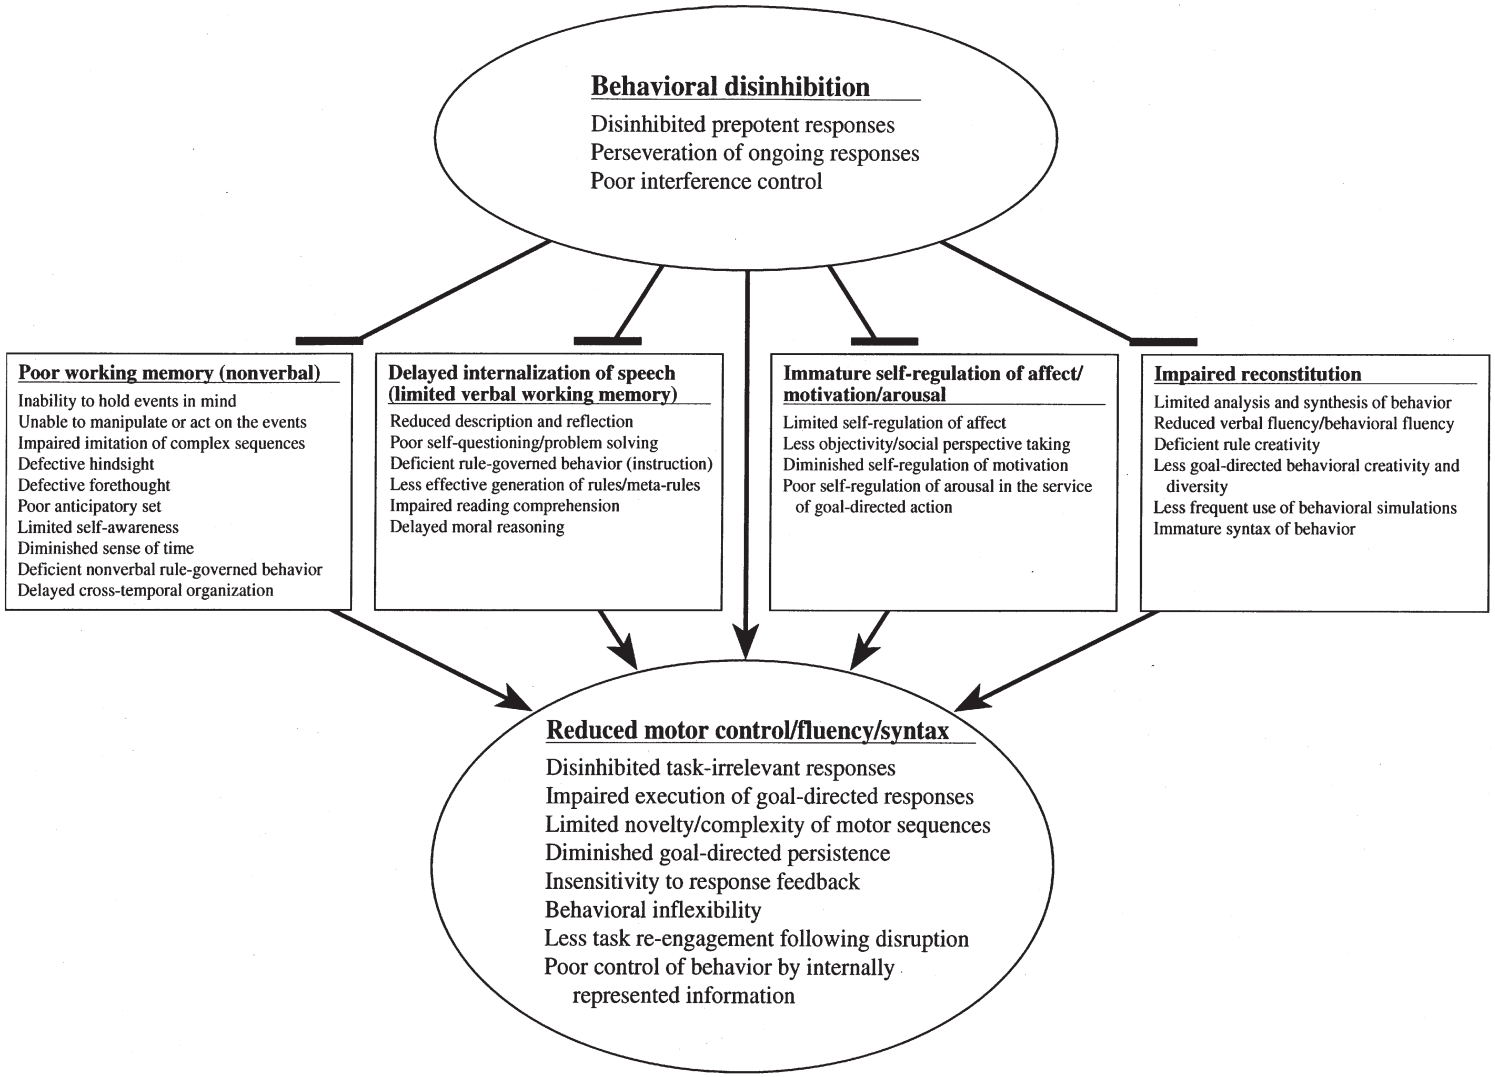

FIGURE 2.2. Diagram illustrating the original hybrid model of executive functions (boxes) and the relationship of these four functions to the behavioral inhibition and motor control systems. From Barkley (1997b). Copyright 1997 by The Guilford Press. Reprinted by permission.

the formation of friendships, social networks, and other reciprocal forms of social exchange with others to accomplish goals; and (4) strategic/cooperative, in which the lower levels of executive functioning now give rise to cooperative group ventures with like-minded others to accomplish joint goals no individual could attain alone or through trade (reciprocity). In this model, deficits at lower levels radiate upward to produce deficiencies in higher levels in daily life; if severe enough, these deficits may cause this hierarchical arrangement to collapse downward. Since ADHD is viewed as creating primary deficits at the first or instrumental level of executive functioning, it produces radiating effects upward (and outward) on these other zones of extended phenotypic effects.

The most recent theories of ADHD have almost all become explicitly "multiple-pathway" theories. That is, they all acknowledge that parallel developmental streams influence ADHD, that there are probably subgroups of ADHD with different causes, and that components of the syndrome may have distinct inputs. Thus Sonuga-Barke (2005) has argued that inattention is related to a breakdown in executive functioning and response inhibition (located in a neural circuit involving the dorsal striatum and dorsolateral prefrontal cortex), but that hyperactivity–impulsivity is related to a breakdown in motivational responding or reward gradient (located in a neural circuit involving the ventral striatum or nucleus accumbens and ventromedial prefrontal cortex). Although prior models all acknowledged the dialectical nature of top-down and bottom-up processes in self-regulation, this theory has the virtue of attempting to integrate the top-down and bottom-up aspects in a parallel model, rather than a sequential model with one component primary.

A novel proposal has also been offered by Nigg and Casey (2005). This theory also integrates multiple neural circuits, including prefrontal–striatal–thalamic circuits involved in cognitive control (which Nigg and Casey refer to as constituting the "what" circuit); frontal–cerebellar circuits involved in learning (which they refer to as composing the "when" circuit); and limbic–frontal circuits involved in emotion regulation and motivation. They have also integrated newer findings from cognitive neuroscience regading the important role of frontal–parietal–subcortical neural circuits in attentional capture and attentional suppression of competing information (the dorsal and ventral attention circuits). Their model, heavily neurobiological in nature, thus integrates several recent developments in the field. In particular, it provides a way to integrate the literature on emotional regulation with the literature on the cognitive neuroscience of attention, and shows how both may be involved in a coordinated way in ADHD. It has also opened the door to computational models of ADHD by specifying prediction functions for these circuits.

Castellanos and Tannock (2002) have offered yet another influential perspective, attempting to tie together the cognitive neuroscience of working memory and cognitive control with the literature on temporal information processing. That work has stimulated further study of working memory and of cerebellar-related time estimation functions in ADHD. It has also renewed interest in response variability in ADHD because these authors have emphasized newer research on response time profiles in ADHD on reaction time tests. Children with ADHD seem to have periodic extremely slow responses, which seem to occur at regular intervals. This is thought to be consistent with abnormal oscillations in the central nervous system. A key and very interesting premise of that model is that slow responses occur at a particular frequency. Karalunas, Huang-Pollock, and Nigg (2013) have recently shown that in fact children with ADHD have slow responses at multiple temporal frequencies, disproving that aspect of the theory. However, the theory will probably continue to stimulate work to understand the pattern of attentional variation over time in ADHD as a crucial bottom-up mechanism.

Nigg and colleagues (2005) have pointed out that no one psychological deficit can account for all cases of ADHD. Rather, different children with ADHD may have distinct underlying neuropsychological or neurobiological mechanisms that account for their problems. In this sense, each hypothesis or theory is capturing a piece of the picture. In support of that model, Nigg and colleagues (Fair, Bathula, Nikolas, & Nigg, 2012) recently conducted a sophisticated mathematical analysis called "community detection" on a large sample of children with ADHD who completed a neuropsychological battery. The model showed that one group of children had problems in response inhibition, another in arousal, and still another in excess response variability. Yet these groups had similar levels of ADHD symptoms.

Overall, the theoretical landscape for ADHD is increasingly rich and sophisticated. We still have very few true theories, but we have at least two that are comprehensive in their predictions (Barkley, 1997a, 2012c; Sagvolden et al., 2005), and many others that provide

strong starting points for understanding ADHD neurobiologically. Major themes in these theories include the importance of dopaminergic circuitry, as well as the effort to articulate an integration of top-down and bottom-up processes in self-regulation and to show how these may break down in ADHD.

IS ADHD A "REAL" DISORDER?

Social critics have been concerned for decades (Breggin, 1998; Kohn, 1989; Schrag & Divoky, 1975; Sroufe, 2012) that professionals may be too quick to label energetic and exuberant children as having a mental disorder. They also assert that educators may be using these labels as an excuse for poor home or educational environments. In other words, children who are diagnosed with hyperactivity or ADHD are actually typical children, but are being labeled as mentally disordered because of parent and teacher intolerance (Kohn, 1989), mismanagement, or lack of love at home (Breggin, 1998). While such instances no doubt sometimes occur, it is difficult to reconcile such claims with the array of biological correlates identified in ADHD: Children with ADHD have reliably reduced brain size (Castellanos et al., 2002) from age 4 on, slower maturation of the cortical mantle (Shaw, Greenstein, et al., 2006), elevated levels of lead in their blood (Nigg et al., 2008), more family members with ADHD (Stawicki et al., 2006), and differences in genotype (Banaschewski, Becker, Scherag, Franke, & Coghill, 2010).

The key problem, to which critics are perhaps alluding, is that the biological markers are not yet sufficient for clinical diagnosis. Diagnosis still relies on clinical judgment about behavioral symptoms. That judgment is only as good as the carefulness of clinical practitioners. The DSM diagnostic criteria are, in essence, not a polemic assertion but a clinical heuristic; they enable clinicians to reliably and validly identify children who are likely to get worse without treatment, who are probably impaired, who are at considerable risk for current and future impairment in multiple domains, and for whom treating is a lesser evil than not treating. The criteria work quite well for these purposes, when properly applied (for detailed support for that claim, see Willcutt et al., 2012).

The ontological status of ADHD as a "real" condition with a definable biological process that can be measured in every case of the disease (as we can do in, say, cancer or influenza) is still some distance off. It is likely that in the long run, if such biomarkers are identified, they will not apply to all individuals currently diagnosed with ADHD. Indeed, for all complex diseases (hypertension, obesity, diabetes, cancer, and psychiatric conditions), the ability to identify a single biological cause is likely to be possible only when we can differentiate subgroups. However, complex disease is inherently characterized by probabilistic prediction based on risk factors that predict morbidity and mortality. ADHD conveys considerable morbidity risk (see below), and thus examination of probabilistic diagnostic categories remains useful. This is likely to remain the state of affairs for the foreseeable future.

EPIDEMIOLOGY

Prevalence

In the past decade, systematic population-based national surveys of ADHD were conducted for the first time. Because of different methods, these did not yield identical results, but they still give a consistent picture of ADHD as a very common condition. In one national survey, the 1-year prevalence rate for children and adolescents was 8.5% (Muthen & Muthen, 2000). Among U.S. adults, the prevalence of ADHD is 4–5% (Barkley, 2012b; Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007). Practitioner surveys by the Centers for Disease Control and Prevention indicate a rising prevalence of ADHD in the United States from the late 1990s to the late 2000s (Boyle et al., 2011), but it is unclear whether this increase is due to true secular trends or to various changes affecting identification. Worldwide, or when data from different countries are pooled, meta-analytic reviews suggest a 1-year prevalence rate of ADHD in children and adolescents of about 5.3% (Polanczyk et al., 2007) and 2–3% in adults (Nylund, Bellmore, Nishina, & Graham, 2007).

However, even these estimates may be high. A sophisticated Baysian analysis that took into account variation in survey and assessment methods and anchored presence of ADHD to a conservative level of clear agreement across two informants estimated ADHD's true prevalence at only 2.2%, with some notable regional variation but no evidence of change in prevalence over the last decade (Erskine et al., 2014). Thus, it remains quite possible that if ADHD is defined conservatively, its prevalence is stable and rather lower than its rate of clinical identification. It is also possible

that this most recent paper defined ADHD too conservatively, and it is possible that over a longer period of several decades ADHD has increased. Furthermore, as those authors acknowledged, survey data are completely lacking in many nations. Thus, the question of true variation in prevalence remains in need of more data.

Although convergent, all of these figures probably represent high estimates of the individuals who have an impairing syndrome that could ultimately be related to a neurobiological injury or abnormality in development. For example, few studies have used *full* DSM-IV or DSM-5 criteria, obtained multiple informants, carefully assessed impairment, or ruled out the possibility that the observed symptoms were actually fully explainable by a co-occurring medical or psychiatric condition. Prevalence rates are much lower for ICD-10 criteria (typically about 1%; Döpfner et al., 2008), due largely to ICD-10's exclusion of children with comorbid mood or behavioral conditions. It is unknown what the prevalence will be for the revised definition in ICD-11.

Sex Differences

As with most psychiatric/developmental disorders of childhood onset, ADHD shows a male preponderance, on the order of 2:1 or higher (Polanczyk et al., 2007); this ratio drops somewhat, to only 1.6:1 or even 1:1 by adulthood (Nigg, Lewis, Edinger, & Falk, 2012), perhaps due in part to underidentification of girls in childhood. Boys are referred for treatment at much higher rates than girls, in part because of higher levels of aggression. In addition, the larger sex difference in childhood may be an artifact of criteria that were developed on the basis of predominantly male samples. Girls may be more likely to display inattentive behaviors, yet whether they show a greater number of comorbid internalizing problems is controversial. Studies of clinically referred girls and boys with ADHD indicate that they show comparable levels of impairment in academic and social functioning, but girls with the disorder may have greater intellectual deficits (Gaub & Carlson, 1997). In community samples, however, girls are less likely to have comorbid externalizing problems than boys, and they do not show greater intellectual impairment (Gaub & Carlson, 1997). With regard to cognitive and biological correlates, girls with ADHD show patterns of impairments in executive functioning and cognitive control similar to those of their male counterparts (Hinshaw, Carte, Sami, Treuting, & Zupan, 2002; Rucklidge & Tannock, 2001). In a major series of clinical cases, girls and boys with ADHD showed similar patterns of impairment on measures of set shifting and interference control, and both groups performed significantly worse than sex-matched controls (Seidman et al., 2005). Doyle and colleagues (2005) reported patterns of neuropsychological impairment in family members of girls with ADHD that were similar to those seen in the relatives of boys with the disorder. These types of results (along with longitudinal studies of symptom severity over development) suggest that important similarities exist between manifestations of ADHD in boys and girls, and that the same construct is being captured (Lahey et al., 2007; Monuteaux, Mick, Faraone, & Biederman, 2010).

Recent large longitudinal studies of girls with ADHD followed from childhood to early adulthood indicate many similarities in the elevation of risks for various impairments between girls and boys with the disorder (Hinshaw et al., 2012; Owens, Hinshaw, Lee, & Lahey, 2009), such as risks for academic performance problems, comorbidity for learning disorders, and peer problems or even rejection, among others. However, some important differences in risk may exist: Girls (especially those with a predominantly inattentive presentation) may have even more difficulties than boys with ADHD in academic performance and peer relationships (Elkins, Malone, Keyes, Iacono, & McGue, 2011). One also finds an increased likelihood of eating pathology (mainly binge eating and higher risk for bulimia), anxiety, and depression among girls and women with ADHD than among males with the disorder (Barkley et al., 2008; Lahey et al., 2007), and these difficulties may be more stable across development into adolescence in girls with ADHD than in boys (Monuteaux et al., 2010). However, both sexes are more prone to these disorders than are typically developing children or adults in the general population (Barkley et al., 2008; Lahey et al., 2007; Monuteaux et al., 2010). Males with ADHD are also more likely than females to engage in antisocial activities, certain forms of substance use disorders, and risky driving with associated adverse outcomes (Barkley et al., 2008; Nussbaum, 2012). Yet here again, both sexes demonstrate higher levels of these difficulties than do comparison groups of same-sex children (Barkley et al., 2008).

However, key issues remain. It is unclear whether sex-specific cutoffs should be considered when ADHD is diagnosed in girls (see Petty et al., 2009). Although girls are less active and disruptive than boys overall, the symptom counts used to diagnose ADHD are the

same for both sexes. Hence it is possible that some girls who have fewer than six symptoms on either DSM symptom dimension, yet who are impaired, are missed by current criteria. Second, girls may have greater resistance to the etiological factors that cause ADHD. In a twin study, Rhee, Waldman, Hay, and Levy (2008) found evidence consistent with this differential threshold model, suggesting that girls with ADHD need more risk genes before manifesting ADHD. Further studies that incorporate studies of hormonal and other sex-specific effects in early development will be important to a complete understanding of ADHD. Despite recent advances, ADHD in girls remains less well understood than in boys, and the apparent equalizing of prevalence in adolescence and adulthood is not well explained.

Socioeconomic Differences

Few studies have examined the relationship of ADHD to socioeconomic status (SES), and those that have are not especially consistent. Lambert, Sandoval, and Sassone (1978) found only slight differences in the prevalence of hyperactivity across SES when parents, teachers, and physicians all agreed on the diagnoses. However, SES differences in prevalence did arise when only two of these three sources had to agree; in this instance, there were generally more children with ADHD from lower- than from higher-SES backgrounds. For instance, when parent and teacher agreement (but not physician agreement) was required, 18% of those identified as hyperactive were from high-SES, 36% from middle-SES, and 45% from low-SES backgrounds. Where only teachers' opinions were used, the percentages were 17%, 41%, and 41%, respectively. Trites (1979), and later Szatmari (1992), both found that rates of ADHD tended to increase with lower SES; however, Szatmari, Offord, and Boyle (1989) found that low SES was no longer associated with rates of ADHD when other comorbid conditions, such as CD, were controlled for. For now, it is clear that ADHD occurs across all socioeconomic levels. Variations across SES may be artifacts of the source used to define the disorder, or of the comorbidity of ADHD with other disorders related to SES (such as ODD and CD).

Ethnic/Cultural/National Issues

Numerous considerations come into play when one considers cultural variation in a syndrome like ADHD, for which abnormality depends heavily on departure from culturally accepted standards of behavior. By way of mental experiment, how would ADHD be defined in an aboriginal culture or a nontechnological hunter–gatherer society? One can still imagine individuals who are very inattentive, impulsive, or severely lacking in self-control being unable to succeed in such a culture, but the behavioral manifestations and societal tolerance for such impairments would probably be quite different. The same caveat probably applies in subtler ways to our efforts to estimate differences in modern cultures.

We begin with prevalence. When using a DSM definition, we can appeal to numerous surveys around the world in the past 20 years. A pooled metaregression analysis by Polanczyk and colleagues (2007) included data from over 170,000 participants in 102 studies on all major populated regions (although the majority of studies have been conducted in North America and Europe). Although these authors found that prevalence varied with assessment method, their final pooled worldwide prevalence rate of 5.3% is quite a plausible one. Across major regions of the world, significant variation was found. Prevalence was highest in South America (11.8%) and Africa (8.5%), and lowest in the Middle East (2.4%), though these differences were nonsignificant after adjustment for ascertainment differences (i.e., differences in how ADHD was assessed). Furthermore, few studies were available in these three regions, so confidence intervals encompassed too wide a range to enable differentiation across them. Regions with enough data for narrow confidence intervals all had similar prevalences (North America, 6.3%; Europe, 4.7%; Oceania, 4.6%; Asia, 3.7%), although these might be significantly different with enough data points.

As noted earlier, a more extensive analysis was undertaken by Erskine and colleagues (2014). This statistically more powerful study did detect reliable regional variation. Rates were highest in North Africa/Middle East and in Oceania, and lowest in South Asia. Again, however, this analysis relied on substantial data imputation given the scarcity of data in many of these regions. Even so, the suggestion of regional variation in true prevalence could, if better pinpointed, provide important clues to etiology and to disease modifiers.

Pinpointing local variation will be crucial, however. Variation within regions or countries (e.g., urban–rural differences) might be extremely important and even more important than variation across countries or regions. But within-country data were not analyzed in any of these studies, due to the reduced sample size of

available studies. Thus additional prevalence data will be important to etiological theories. For example, if lead exposure, anemia, or malnutrition contributes to ADHD, then prevalence should be somewhat higher in regions, nations, or localities with higher exposures (e.g., South Africa), unless these effects are countered by alternative etiologies in developed nations (e.g., higher rates of surviving children with low birth weight). Even so, rates of stimulant treatment are up to twice as high or more in the United States as in many other nations, due to differences in historical approach, laws, and professional practice (Giles et al., 1997); other wealthy nations are on a similar use trajectory (Steckler, Goodman, & Alciati, 1997).

Beyond prevalence, however, several complexities are worthy of comment. First, ADHD-related behaviors may not have the same meaning in the eyes of teachers and parents across cultural groups. For example, Mann and colleagues (1992) found that clinicians of different cultures rated the same child actors at significantly different symptom levels even when faced with identical behaviors (independent of the race of each child). On the other hand, Epstein and colleagues (2008) found that teachers' ratings of excess ADHD symptoms in African American children were consistent with behavioral observations of the same classrooms. This main effect of race was partially due to the fact that African American children were more often in classrooms where the average child had more misbehavior. The paucity of research on these issues represents a gaping hole in our knowledge base.

Second, it is unclear to what extent the ADHD syndrome has similar internal validity across ethnic or cultural groups, or under what conditions this might change. Data suggest that the ADHD symptom factor structure is essentially the same across nations (Goodman, Steckler, & Alciati, 1997). Reid and associates (1998) examined the factor loadings of ADHD symptoms in African American and European American children in the United States. Although the general two-factor symptom structure was preserved across groups, the item loadings differed, suggesting that the syndrome might have a different meaning in the two groups. African American children are often identified at different rates than European American children, but the reasons for this are unclear (Miller, Nigg, & Miller, 2009). It is not difficult to imagine how the same behavior could have different meanings across U.S. racial groups (e.g., one might speculate that an African American child more often may be socialized to call out in groups, whereas a European American child may be socialized to remain quiet or wait his or her turn in large groups). Different meanings across nations are also plausible.

Still, countering such suppositions, the major review by Rohde and colleagues (1999) concluded that studies in developing nations yield factor structures, treatment responses, prevalences, and biological correlates similar to those of studies in developed nations—a conclusion supporting the cross-cultural validity of ADHD. Such evidence raises the question of when, if at all, racially or culturally specific norms should be included in the assessment of ADHD. Again, a paucity of research signifies ripe opportunities for future investigators in this area to clarify local variation or boundary conditions (if any) on the cross-cultural validity of ADHD, and thus to provide a more differentiated map of construct validity.

Third, treatment rates vary radically across nations (Forero, Arboleda, Vasquez, & Arboleda, 2009), and approaches to treatment may be different across cultural groups even within the United States (Kandziora et al., 2003). Data are lacking on the important issue of whether this discrepancy leads to an excess of poor outcomes among minority children. These differences in services may reflect reduced access to care, or they may reflect distinct attitudes toward the diagnostic and treatment infrastructure. Further empirical work is needed on such issues as costs, access to care, attitudes/beliefs, and differential outcomes.

In particular, we would be interested to see more work on the effects of race of child, race of informant, and race of provider on ratings of child behavior using standardized probes (e.g., child actors). Race entails cultural variation (in some cases) as well as stereotype effects, and disentangling these will be extremely valuable to improving culturally competent assessment in an increasingly diverse society.

DEVELOPMENTAL COURSE AND ADULT OUTCOME

Major follow-up studies into adulthood of clinically referred children with hyperactivity or ADHD have been ongoing during the last 40 years at many sites: (1) Montreal (Weiss & Hechtman, 1993); (2) New York City (Gittelman, Mannuzza, Shenker, & Bonagura, 1985; Klein et al., 2012; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1993); (3) Iowa City (Loney, Kramer, &

Milich, 1981); (4) Los Angeles (Satterfield, Hoppe, & Schell, 1982); (5) Milwaukee (Barkley et al., 2008); (6) San Francisco (Lee, Lahey, Owens, & Hinshaw, 2008); (7) Boston (Biederman, Faraone, Milberger, et al., 1996; Biederman, Petty, Evans, Small & Faraone, 2010); and (8) Rochester, Minnesota (Barbaresi et al., 2013). Follow-up studies of children identified as hyperactive from a general population have also been conducted in the United States (Lambert, 1988), New Zealand (McGee, Williams, & Silva, 1984; Moffitt, 1990), and England (Taylor, Sandberg, Thorley, & Giles, 1991), among others. Many other follow-up studies of shorter duration (such as from childhood to adolescence) have also been published in the last decade; these are too numerous to list here.

But before we proceed, some cautionary notes are in order. First, most of the long-term follow-up studies began prior to the current DSM-based definitions of ADHD, and so estimates may vary as to the degree of overlap with children defined by current criteria. Most of the earliest studies selected for children known at the time as "hyperactive." Such children are most likely representative of those diagnosed with ADHD, combined type/presentation, in the current DSM taxonomy. Even then, the degree of deviance of the samples on parent and teacher ratings of these symptoms was not established at the entry point in most of these studies. These studies also cannot be viewed as representing the predominantly inattentive type/presentation of ADHD or SCT, for which no follow-up information is currently available. The descriptions of clinic-referred children with ADHD who are of similar age groups to those in the follow-up studies, but who are not followed over time, may help us understand the risks associated with different points in development.

Second, to the extent that the context for children's development is rapidly changing and affecting attention and externalizing problems (e.g., screen media and violent video games; two- parent working households), studies of children recruited some decades ago may not be fully relevant to present-day children. Such cohort effects may be minor in some respects; at least in the past, for example, adolescents with ADHD referred to clinics seemed to have types and degrees of impairment similar to those of children with ADHD followed up to adolescence (cf. Barkley, Anastopoulos, Guevremont, & Fletcher, 1991; Barkley, Fischer, Edelbrock, & Smallish, 1990). This is also the case for the most part with clinic-referred adults versus children followed to adulthood (Barkley et al., 2008), but in this case the children followed to adulthood had more severe adverse outcomes in some areas (education, work) than did adults currently referred to clinics receiving a diagnosis.

Third, discontinuities of measurement that exist in these follow-up studies between their different points of assessments make straightforward conclusions about developmental course difficult. Fourth, the differing sources of children greatly affect the outcomes to be found, with children drawn from clinic-referred populations having two to three times the occurrence of some negative outcomes and more diverse negative outcomes as those drawn from population screens have had (e.g., cf. Barkley, Fischer, et al., 1990; Lambert, 1988), although in a more recent instance the results were similar (cf. Barkley et al., 2008; Barbaresi et al., 2013). Generalizing from the clinic-recruited samples to the general population is not straightfoward.

We concentrate here on the course of the disorder itself, returning to the comorbid disorders and associated conditions likely to arise in the course of ADHD in a later section of this chapter ("Comorbid Psychiatric Disorders").

The average onset of ADHD symptoms, as noted earlier, is often in the preschool years, typically at ages 3–4 (Applegate, Lahey, Hart, Waldman, Biederman et al., 1997; Loeber et al., 1992; Taylor et al., 1991) and more generally by entry into formal schooling. Yet onset is heavily dependent on the type of ADHD under study. First to arise is the pattern of hyperactive– impulsive behavior (and, in some cases, oppositional and aggressive conduct), giving that subtype the earliest age of onset. The combined type of ADHD has an onset within the first few grades of primary school (ages 5–8; Hart et al., 1995), most likely due to the requirement that both hyperactivity and inattention must be present for this subtype to be diagnosed. Predominantly inattentive ADHD appears to emerge a few years later (ages 8–12) than the other types (Applegate et al., 1997).

Preschool-age children who are perceived as difficult and resistant to control, or who have inattentive and hyperactive behavior that persists for at least a year or more, are highly likely to have ADHD and to remain so into elementary school years (Beitchman et al., 1987; Campbell, 2006; Palfrey et al., 1985) and even adolescence (Olson, Bates, Sandy, & Lanthier, 2000). Persistent cases seem especially likely to occur where parent–child conflict, greater maternal directiveness and negativity, and greater child defiant behavior or frank ODD exist (Campbell, March, Pierce, Ewing, &

Szumowski, 1991; Olson et al., 2000; Richman, Stevenson, & Graham, 1982). More negative temperament and greater emotional reactivity to events are also more common in preschool children with ADHD (Barkley, DuPaul, & McMurray, 1990; Campbell, 2006). It is little wonder that greater parenting stress is associated with having preschool children with ADHD, and such stress seems to be at its highest with preschoolers relative to later age groups (Mash & Johnston, 1983a, 1983b). Within the preschool setting, children with ADHD will be found to be more often out of their seats, wandering the classroom, being excessively talkative and vocally noisy, and disruptive of other children's activities (Campbell, Schleifer, & Weiss, 1978; Schleifer et al., 1975).

By the time children with ADHD move into the elementary-school-age range of 6–12 years, the problems with hyperactive–impulsive behavior are likely to continue and to be joined now by difficulties with attention (executive functioning and goal-directed persistence). Difficulties with work completion and productivity; distraction; forgetfulness related to what needs doing; lack of planning; poor organization of work activities; and trouble meeting time deadlines associated with home chores, school assignments, and social promises/commitments to peers are now combined with the impulsive, heedless, and disinhibited behavior typifying these children since preschool age. Problems with oppositional and socially aggressive behavior may emerge at this age in at least 40–70% of children with ADHD (Loeber, Burke, Lahey, Winters, & Zera, 2000; Loeber, Burke, & Pardini, 2009; Loeber et al., 1992; Taylor et al., 1991).

By ages 8–12 years, these early forms of defiant and hostile behavior or outright ODD may evolve further into symptoms of CD in 25–45% or more of all children with ADHD, if CD was not present already (Barkley, Fischer, et al., 1990; Gittelman et al., 1985; Loeber et al., 1992; Mannuzza et al., 1993; Taylor et al., 1991). Certainly by late childhood, most or all of the deficits in the executive functions related to inhibition in the model presented earlier are likely to be arising and interfering with adequate self-regulation (Barkley, 1997a). Not surprisingly, the overall adaptive functioning (self-sufficiency) of many children with ADHD (Stein, Szumowski, Blondis, & Roizen, 1995) is significantly below their intellectual ability. This is also true of preschoolers with high levels of these externalizing symptoms (Barkley, Shelton, et al., 2002). The disparity between adaptive functioning and age-appropriate expectations (or IQ) may itself be a predictor of greater severity of ADHD, as well as risk for oppositional and conduct problems in later childhood (Shelton et al., 1998). The disorder takes its toll on self-care, personal responsibility, chore performance, trustworthiness, independence, and appropriate social skills, as well as on doing tasks on time specifically and moral conduct generally (Barkley, 2006; Hinshaw et al., 1993).

If ADHD is present in clinic-referred children, the likelihood is that 50–80% will continue to have their disorder into adolescence, with most studies supporting the higher figure (August, Stewart, & Holmes, 1983; Claude & Firestone, 1995; Barkley, Fischer, et al., 1990; Gittelman et al., 1985; Lee et al., 2008; Mannuzza et al., 1993). Using the same parent rating scales at both the childhood and adolescent evaluation points, Fischer and colleagues (1993b) were able to show that inattention, hyperactive–impulsive behavior, and home conflicts declined by adolescence. The hyperactive group showed far more marked declines than the control group, mainly because the former were so far from the mean of the normative group to begin with in childhood. Nevertheless, even at adolescence the groups remained significantly different in each domain, with the mean for the hyperactive group remaining two standard deviations or more above the mean for the controls. This emphasizes a point made earlier: Simply because severity levels of symptoms are declining over development, this does not mean that children with ADHD are necessarily outgrowing their disorder relative to normal children. Like intellectual disabilities, ADHD may need to be defined as a developmentally relative deficiency rather than an absolute one, and a deficiency that persists in most children over time.

The persistence of ADHD symptoms across childhood as well as into early adolescence appears, again, to be associated with initial degree of hyperactive–impulsive behavior in childhood; the coexistence of conduct problems or oppositional hostile behavior; poor family relations (specifically, conflict in parent–child interactions); and maternal depression, as well as duration of maternal mental health interventions (Fischer et al., 1993a; Taylor et al., 1991). These predictors have also been associated with the development and persistence of ODD and CD into this age range (12–17 years; Barkley et al., 2008; Fischer et al., 1993a; Loeber, 1990; Mannuzza & Klein, 1992; Taylor et al., 1991).

Studies following large samples of clinic-referred children with hyperactivity or ADHD into adulthood

are few in number. Only seven follow-up studies have retained 50% or more of their original samples from childhood into adulthood and reported on the persistence of symptoms to that time. These are the Montreal study by Weiss, Hechtman, and their colleagues (see Weiss & Hechtman, 1993); the New York City study by Mannuzza, Klein, and colleagues (see Klein et al., 2012; Mannuzza et al., 1993; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1998); the Swedish study by Rasmussen and Gillberg (2001); Barkley's research with Mariellen Fischer in Milwaukee (Barkley et al., 2008); the Rochester, Minnesota study (Barbaresi et al., 2013); and the Boston study (Biederman et al., 2010). Results regarding the persistence of disorder into young adulthood (middle 20s) are mixed, but can be understood as being a function of reporting source and the diagnostic criteria used (Barkley, Fischer, Smallish, & Fletcher, 2002).

The Montreal study (n = 103) found that two-thirds of the original sample (n = 64; mean age = 25 years) claimed to be troubled as adults by at least one or more disabling core symptoms of their original disorder (restlessness, impulsivity, or inattention), and that 34% had at least moderate to severe levels of hyperactive, impulsive, and inattentive symptoms (Weiss & Hechtman, 1993). In Sweden (n = 50), Rasmussen and Gillberg (2001) obtained similar results, with 49% of probands reporting marked symptoms of ADHD at age 22 years compared to 9% of controls. Formal diagnostic criteria for ADHD, such as those in DSM-III or later editions, were not employed at any of the outcome points in either study, however. In contrast, the New York study has followed two separate cohorts of hyperactive children, using DSM criteria to assess persistence of disorder. That study found that 31% of the initial cohort (n = 101) and 43% of the second cohort (n = 94) met DSM-III criteria for ADHD by ages 16–23 (mean age = 18.5 years) (Gittelman et al., 1985; Mannuzza et al., 1991). Eight years later (mean age = 26 years), however, these figures fell to 8% and 4%, respectively (with DSM-III-R criteria now being used) (Mannuzza et al., 1993, 1998). These authors reported the prevalence of ADHD by age 40 to be 22% vs. 5% in the control group (Klein et al., 2012). If more adult-sensitive diagnostic thresholds are used (say, four instead of six symptoms, as discussed above), then persistence of full disorder was 32%. The uptick in prevalence from the last follow-up to this one is due in part to relying on self-reported symptoms, which are often underreported in early adulthood but increase with age (Barkley et al., 2008). The recent follow-up study in Rochester, Minnesota (Barbaresi et al., 2013), like the Milwaukee study, followed the children to age 27 or older. It reported a 29% persistence of disorder to young adulthood. These results might imply that the vast majority of hyperactive children no longer qualify for the diagnosis of ADHD by adulthood.

The interpretation of the relatively low rate of persistence of ADHD into adulthood is clouded by at least two issues, apart from differences in selection criteria. One is that the source of information about the disorder changed in all of these studies from that used at the childhood and adolescent evaluations to that used at the adult outcome. At study entry and at adolescence, all studies used the reports of others (parents and typically teachers); all found that the majority of hyperactive participants (50–80%) continued to manifest significant levels of the disorder by midadolescence (see above). In young adulthood (approximately age 26 years), however, most studies switched to self-reports of disorder. Changing sources of reporting in longitudinal studies on behavioral disorders can be expected to lead to marked differences in estimates of persistence of those disorders (Barkley, Fischer, et al., 2002; Barkley et al., 2008).

The question obviously arises: Whose assessment of the probands is more accurate? This would depend on the purpose of the assessment, but the prediction of impairment in major life activities would seem to be an important one in research on psychiatric disorders. The Milwaukee study examined these issues by interviewing both the participants and their parents about ADHD symptoms at the young adult follow-up (age 21 years). It then examined the relationship of each source's reports to significant outcomes in major life activities (education, occupation, social, etc.), after controlling for the contribution made by the other source. As noted earlier, another limitation in the earlier studies may reside in the DSM criteria, in that these grow less sensitive to the disorder with age. Using a developmentally referenced criterion (age comparison) to determine diagnosis might identify more cases than would the DSM approach. As discussed earlier, the Milwaukee study found that the persistence of ADHD into adulthood was heavily dependent on the source of the information (self or parent) and the diagnostic criteria (DSM or developmentally referenced). Self-report identified just 5–12% of probands as currently having ADHD (DSM-III-R), whereas parent reports placed this figure at 46–66%. Using the DSM resulted in lower rates of persistence (5% for proband reports and 46% for par-

ents), whereas using a developmentally referenced cutoff (98th percentile) yielded higher rates of persistence (12% by self-reports and 66% by parent reports). The parent reports appeared to have greater validity, in view of their greater contribution to impairment and to more domains of current impairment, than did self-reported information (Barkley, Fischer, et al., 2002). We have concluded that past follow-up studies underestimated the persistence of ADHD into adulthood by relying solely on the self-reports of the probands, especially in young adulthood, while not obtaining corroborative information from others who know the cases well.

COMORBID PSYCHIATRIC DISORDERS

Individuals diagnosed with ADHD often have other disorders besides their ADHD. What is known about comorbidity is largely confined to the combined type/presentation of ADHD. In community-derived samples, up to 44% of children with ADHD have at least one other disorder, and 43% have at least two or more additional disorders (Willcutt et al., 2012). The figure is higher, of course, for children seen in clinics, where as many as 80–87% may have at least one other disorder (Kadesjo & Gillberg, 2001). This is also true for clinic-referred adults with ADHD (Barkley et al., 2008). The disorders likely to co-occur with ADHD are briefly described below.

Conduct Problems and Antisocial Disorders

Disruptive or externalizing behavior problems are the most common co-occuring domain for ADHD. In this group, the most common disorder is ODD, with CD following some distance behind in a subset. The presence of ADHD increases the odds of ODD/CD by 10.7-fold (95% confidence interval [CI] = 7.7–14.8) in general population studies (Angold, Costello, & Erkanli, 1999). Studies of clinic-referred children with ADHD find that between 54 and 67% will meet criteria for a diagnosis of ODD by 7 years of age or later. One possible reason for this heightened comorbidity has been proposed by Barkley (2010) as a causal one, given that ODD is bi- or tridimensional in nature (see Kimonis, Frick, & McMahon, Chapter 3, this volume) and that one of those dimensions involves emotional dysregulation (anger, temper, irritability, etc.). Barkley has made the case that ADHD involves a significant deficit in the self-regulation of emotion, and that it is through this pathway that ADHD heightens risk for the emotional dysregulation element of ODD.

ODD is a frequent precursor to or co-occurring disorder with CD, a more severe and often (though not always) later-occurring stage of ODD (Loeber et al., 2000, 2009). The co-occurrence of CD with ADHD may be 20–50% in children and 44–50% in adolescents with ADHD (Barkley, 2006; Barkley, Fischer, et al., 1990; Biederman, Faraone, & Lapey, 1992; Lahey, McBurnett, & Loeber, 2000). By adulthood, up to 26% may continue to have CD, while 12–21% will qualify for a diagnosis of antisocial personality disorder (ASPD) (Barbaresi et al., 2013; Barkley et al., 2008; Biederman et al., 1992; Klein et al., 2012; Mannuzza & Klein, 1992; Rasmussen & Gillberg, 2001; Weiss & Hechtman, 1993). Similar or only slightly lower degrees of overlap are noted in studies using epidemiologically identified samples rather than those referred to clinics.

ADHD therefore has a strong association with ODD, CD, and ASPD, and is one of the most reliable early predictors of these disorders (Fischer et al., 1993a; Kimonis et al., Chapter 3, this volume; Lahey et al., 2000). Indeed, at least in boys, it is almost invariably the case that when CD is observed, ADHD has preceded it. Recent longitudinal research suggests that severity of early ADHD is actually a contributing factor to risk for later ODD, regardless of severity of early ODD (Burns & Walsh, 2002; Loeber et al., 2009), perhaps due to the problems with poor emotion (anger) regulation in ADHD noted above (Barkley, 2010). Familial associations among the disorders have also been consistently found, whether across boys and girls with ADHD or across European American and African American samples (Biederman et al., 1995; Faraone et al., 2000; Samuel et al., 1999). This suggests some underlying causal connection among these disorders.

Evidence from twin studies indicates a shared or common genetic contribution to ADHD, ODD, and CD, particularly between ADHD and ODD (Coolidge, Thede, & Young, 2000; Silberg et al., 1996; Tuvblad, Zheng, Raine, & Baker, 2009). When CD occurs in conjunction with ADHD, it may represent simply a more severe form of ADHD having a greater family genetic loading for ADHD (Thapar, Harrington, & McGuffin, 2001). Other research, however, suggests that a shared environmental risk factor may also account for the overlap of ODD and CD with ADHD beyond their shared genetics (Burt, Krueger, McGue, & Iacono, 2001); this risk factor is likely to be family adversity

generally and impaired parenting specifically (Patterson, Degarmo, & Knutson, 2000). To summarize, ODD and CD have a substantial likelihood of co-occurring with ADHD, and the risk for ODD/CD seems to be mediated in large part by severity of ADHD and its family genetic loading and in part by adversity in the familial environment.

Substance Use Disorders

ADHD is a powerful risk factor for future substance use disorders (SUDs) (Charach, Yeung, Climans, & Lillie, 2011; Lee, Humphreys, Flory, Liu, & Glass, 2011). One of the strongest predictors of risk for SUDs among children with ADHD upon reaching adolescence and adulthood is prior or coexisting CD or ASPD (Burke, Loeber, & Lahey, 2001; Charach et al., 2011; Chilcoat & Breslau, 1999; Molina & Pelham, 1999; White, Xie, Thompson, Loeber, & Stouthamer-Loeber, 2001). Given the heightened risk for ODD/CD/ASPD in children with ADHD as they mature, one would naturally expect a greater risk for SUDs as well. Although an elevated risk for alcohol abuse has not been documented in all follow-up studies, it has been seen in many (Barkley et al., 2008). The risk for other SUDs among hyperactive children followed to adulthood ranges from 12 to 24% (Barbaresi et al., 2013; Barkley et al., 2008; Gittelman et al., 1985; Klein et al., 2012; Mannuzza et al., 1993, 1998; Rasmussen & Gillberg, 2001). One longitudinal study of hyperactive children suggested that childhood treatment with stimulant medication may predispose youth to develop SUDs (Lambert & Hartsough, 1998). All other longitudinal studies, however, find no such elevated risk, and in some cases even a protective effect if stimulant treatment is continued for a year or more or into adolescence (Barkley, Fischer, Smallish, & Fletcher, 2003). The basis for the conflicting findings in the Lambert and Hartsough (1998) study was probably not examining or statistically controlling for severity of ADHD and CD at adolescence and young adulthood (Barkley et al., 2003).

Anxiety and Mood Disorders

The overlap of anxiety disorders with ADHD has been found to range from 10 to 40% in clinic-referred children, averaging about 25% (for reviews, see Jarrett & Ollendick, 2008; Shatz & Rostain, 2006; Tannock, 2000). In longitudinal studies of children with ADHD, however, the risk of anxiety disorders is no greater than in control groups at either adolescence or young adulthood (Barkley et al., 2008; Mannuzza et al., 1993, 1998; Russo & Beidel, 1994; Weiss & Hechtman, 1993). In some follow-up studies the rate increases with age (Barkley et al., 2008); in others, especially in midlife, it is not different from that of controls (Klein et al., 2012). The disparity in findings is puzzling. Perhaps some of the overlap of ADHD with anxiety disorders in children is due to referral bias (Biederman et al., 1992; Tannock, 2000). General population studies of children, however, do suggest an elevated odds ratio of having an anxiety disorder in the presence of ADHD of 3.0 (95% CI = 2.1–4.3), with this relationship being significant even after researchers control for comorbid ODD/CD (Angold et al., 1999). This implies that the two disorders may have some association apart from referral bias, at least in childhood. The co-occurrence of anxiety disorders with ADHD has been shown to reduce the degree of impulsiveness, relative to ADHD without comorbid anxiety disorders (Pliszka, 1992). Some research suggests that the disorders are transmitted independently in families and so are not linked to each other in any genetic way (Biederman, Newcorn, & Sprich, 1991; Last, Hersen, Kazdin, Orvaschel, & Perrin, 1991). This may not be the case for predominantly inattentive ADHD or especially for SCT. Higher rates of anxiety disorders have been noted in some studies of these children (see Milich et al., 2001), and in their first- and second-degree relatives (Barkley, DuPaul, & McMurray, 1990; Biederman et al., 1992), though again not always (Lahey & Carlson, 1992; Milich et al., 2001). Regrettably, research on the overlap of anxiety disorders with ADHD has generally chosen to consider the various anxiety disorders as a single group in evaluating this issue. Greater clarity and clinical utility from these findings might occur if the types of anxiety disorders present were to be examined separately.

The evidence for the co-occurrence of mood disorders as defined in earlier editions of DSM (i.e., depressive disorders; we omit discussion of bipolar disorder in this paragraph) with ADHD is now fairly substantial (Biederman et al., 2008; Faraone & Biederman, 1997; Jensen, Martin, & Cantwell, 1997; Jensen, Shervette, Xenakis, & Richters, 1993; Spencer, Wilens, Biederman, Wozniak, & Harding-Crawford, 2000), although such comorbidity only exists in a minority of individuals with ADHD. Most studies place the association for depression with ADHD between 20 and 30% of ADHD cases (Barkley et al., 2008; Biederman et al., 1992; Cuffe et al., 2001) with risk possibly increasing into

adolescence and early adulthood (Barkley et al., 2008). The odds ratio of having depression, given the presence of ADHD in general population samples, is 5.5 (95% CI = 3.5–8.4) (Angold et al., 1999). As discussed above under "Sex Differences," the risk for depression appears to be higher in girls than in boys with ADHD, although both experience higher risk than do typically developing children. It is possible that some of the overlap between ADHD and depression is mediated by the increased deficits in emotion regulation associated with ADHD (especially for irritability, as discussed above, which is also a symptom of depression but can also be seen in ADHD and other disorders).

Some evidence also suggests that these disorders may be genetically related to each other (Cole, Ball, Martin, Scourfield, & McGuffin, 2009), with familial risk for one disorder substantially increasing the risk for the other (Biederman, Faraone, Keenan, & Tsuang, 1991; Biederman, Newcorn, & Sprich, 1991; Faraone & Biederman, 1997), particularly in cases where ADHD is comorbid with CD. Supportive of this mediational role of CD, one follow-up study (Barkley et al., 2008) found a 26% risk of major depression among children with ADHD by young adulthood, but this risk was largely mediated by the co-occurrence of CD. Likewise, a meta-analysis of general population studies indicated that the link between ADHD and depression was entirely mediated by the linkage of both disorders to CD (Angold et al., 1999). In the absence of CD, ADHD was not more likely to be associated with depression. This has also been shown in some follow-up studies of ADHD children into adolescence (Bagwell, Molina, Kashdan, Pelham, & Hoza, 2006).

The comorbidity of ADHD with bipolar (manic–depressive) disorders has been controversial over the past 25 years (Carlson, 1990; Geller & Luby, 1997; Skirrow, Hosang, Farmer, & Asherson, 2012). Some studies of children with ADHD indicate that 10–20% may have a bipolar disorder (Spencer et al., 2000; Wozniak et al., 1995)—a figure substantially higher than the 1% risk for the general population (Lewinsohn, Klein, & Seeley, 1995). However, this has not held up when examined by others; for instance, Hassan, Agha, Langley, and Thapar (2011) found less than 1% of their ADHD sample would meet criteria for mania. Follow-up studies have not documented any significant increase in risk of bipolar disorders in children with ADHD followed into adulthood (Barbaresi et al., 2013; Barkley et al., 2008; Klein et al., 2012; Mannuzza et al., 1993, 1998; Skirrow et al., 2012; Weiss & Hechtman, 1993); however, given small sample sizes that risk would have to exceed 7% for these studies to have sufficient power to detect any comorbidity. Children with ADHD may therefore have slightly elevated risks for bipolar disorders (Skirrow et al., 2012; Youngstrom, Arnold, & Frazier, 2010). A 4-year follow-up of children with ADHD reported that 12% met criteria for a bipolar disorder in adolescence (Biederman, Faraone, Mick, et al., 1996). Children with ADHD but without bipolar disorder do not always have an increased prevalence of bipolar disorders among their biological relatives (Biederman et al., 1992; Faraone, Biederman, & Monuteaux, 2001; Lahey et al., 1988) but other reviews have shown such a familial presence of each disorder among relatives of children with the other disorder (Faraone, Biederman, & Wozniak, 2012; Skirrow et al., 2012; Youngstrom et al., 2010). Regardless, children with both ADHD and bipolar disorder do have such an elevated incidence of both disorders among family members (Faraone et al., 1997, 2001). This suggests that where the overlap occurs, it may represent a familially distinct subset of ADHD. Children and adolescents diagnosed with childhood bipolar disorder often have a substantially higher lifetime prevalence of ADHD, particularly in their earlier childhood years (Skirrow et al., 2012; Youngstrom et al., 2010). Where the two disorders coexist, the onset of bipolar disorder may be earlier than in bipolar disorder alone (Faraone et al., 1997, 2001; Sachs, Baldassano, Truman, & Guille, 2000). Some of this overlap with ADHD may be partly an artifact of similar symptoms in the symptom lists used for both diagnoses (hyperactivity, distractibility, poor judgment, etc.) (Geller & Luby, 1997; Youngstrom et al., 2010). In any case, the overlap of ADHD with bipolar disorder appears to be mostly unidirectional: A diagnosis of ADHD seems not to increase the risk for bipolar disorder or does so only slightly, whereas a diagnosis of childhood bipolar disorder seems to dramatically elevate the risk of a prior or concurrent diagnosis of ADHD (Geller & Luby, 1997; Skirrow et al, 2012; Spencer et al., 2000; Youngstrom et al., 2010).

Tourette's Disorder and Other Tic Disorders

Up to 18% of children may develop a motor tic in childhood, but this declines to a base rate of about 2% by midadolescence and less than 1% by adulthood (Peterson, Pine, Cohen, & Brook, 2001). Tourette's disorder, a more severe disorder involving multiple motor and vocal tics, occurs in less than 0.4% of the population

(Peterson et al., 2001). A diagnosis of ADHD may elevate somewhat the risk for tic disorders or Tourette's disorder (Simpson, Jung, & Murphy, 2011), but the point is arguable (Peterson et al., 2001). Among clinic-referred adults diagnosed with ADHD, there may be a slightly greater occurrence of tic disorders (12%; Spencer et al., 2001). In contrast, individuals with obsessive–compulsive disorder or Tourette's disorder have a marked elevation in risk for ADHD—up to 55% (Freeman, 2007), and averaging 48% or more (range = 35–71%; Comings, 2000; Simpson et al., 2011). Complicating matters is the fact that the onset of ADHD often seems to precede that of Tourette's disorder in cases of comorbidity (Comings, 2000; Freeman, 2007), and it may result in earlier onset of Tourette's disorder as well as in substantial comorbidity for other disorders (Freeman, 2007).

Autism Spectrum Disorder

DSM-5 now allows codiagnosis of ADHD and autism spectrum disorder (ASD). This is sensible because as many as half of children with ASD may have co-occuring inattention and/or hyperactivity meeting clinical thresholds (van der Meer et al., 2012). A growing literature points to some overlaps in neuropsychological, neuroimaging, and genetic loci associated with these two disorders (Nijmeijer et al., 2010; Rommelse, Franke, Geurts, Hartman, & Buitelaar, 2010; Rommelse et al., 2011).

ASSOCIATED HEALTH OUTCOMES

Health outcomes related to ADHD have recently been reviewed in detail by Nigg (2013). Here we follow that review substantially, while adding other recent findings.

Accident-Proneness and Injury

In one of the first studies of the issue, Stewart, Pitts, Craig, and Dieruf (1966) found that four times as many hyperactive children as control children (43% vs. 11%) were described by parents as accident-prone. Later studies have also identified such risks; up to 57% of children with hyperactivity or ADHD are said to be accident-prone by parents, relative to 11% or fewer of control children (Mitchell, Aman, Turbott, & Manku, 1987). Interestingly, knowledge about safety does not appear to be lower in overactive, impulsive children than in control children. And so simply teaching more information about safety may not suffice to reduce the accident risks of hyperactive children (Mori & Peterson, 1995).

Over a 20-year period, several studies of small, local, or convenience samples found that children with ADHD experienced more injuries of various sorts than control children. For example, one group reported that 16% of the hyperactive sample had at least four or more serious accidental injuries (broken bones, lacerations, head injuries, severe bruises, lost teeth, etc.), compared to just 5% of control children (Hartsough & Lambert, 1985). Jensen, Shervette, Xenakis, and Bain (1988) found that 68% of children with DSM-III ADD, compared to 39% of control children, had experienced physical trauma sufficient to warrant sutures, hospitalization, or extensive/painful procedures. Several other small studies of convenience or local samples likewise found a greater frequency of accidental injuries than among control children (Shelton et al., 1998; Taylor et al., 1991).

More accurate estimates have recently been provided by large-scale population surveys, taking advantage of insurance databases. Common physical traumas among individuals with ADHD include superficial injuries and contusions, open wounds, dislocations, strains, sprains, and fractures of the upper limbs (Marcus, Wan, Zhang, & Olfson, 2008; Merrill, Lyon, Baker, & Gren, 2009). Many studies examining the association between ADHD and unintentional injury rely on medical records, and are therefore limited to those diagnoses that have received medical attention. However, using data from the National Health Interview Survey among more than 50,000 children ages 6–17 years, Pastor and Reuben (2006) examined parent-reported injuries (excluding poisoning) that required consultation with a medical professional. The annualized injury rate in the general population was 115/1,000 (11.5%), but among those ever diagnosed with ADHD, this rate was 204/1000 (20.4%; adjusted odds ratio = 1.83; 95% CI = 1.48–2.26).

Not surprisingly, the types of injuries associated with ADHD appear to vary with individuals' stage of development. In very young children, ADHD and hyperactivity in general are associated with an increased risk of nasal and aural foreign body insertions (Perera, Fernando, Yasawardena, & Karunaratne, 2009). Pediatric patients with ADHD are at increased risk for burns (Badger, Anderson, & Kagan, 2008; Fritz &

Butz, 2007; Perera et al., 2009), and adolescents and adults with ADHD are at risk of auto accidents (Barkley & Cox, 2007) and related injuries (Barkley & Cox, 2007; Barkley, Murphy, DuPaul, & Bush, 2002; Barkley, Murphy, & Kwasnik, 1996a), as discussed next, due to poorer driving including more traffic violations and license suspensions (Barkley & Cox, 2007; Barkley, Guevremont, Anastopoulos, DuPaul, & Shelton, 1993; Jerome, Segal, & Habinski, 2006).

Driving Risks and Auto Accidents

The most extensively studied form of accidents occurring among those with hyperactivity or ADHD is motor vehicle crashes. Evidence emerged years ago that hyperactive teens as drivers had a higher frequency of vehicular crashes than control teens (1.3 vs. 0.07; $p < .05$) (Weiss & Hechtman, 1993). Also noteworthy in their driving histories was a significantly greater frequency of citations for speeding. Subsequently, Barkley and colleagues (1993) found that teens with ADHD had more crashes as drivers (1.5 vs. 0.4) than did control teens over their first few years of driving. Forty percent of the group with ADHD had experienced at least two or more such crashes, relative to just 6% of the control group. Four times more teens with ADHD were deemed to have been at fault in their crashes as drivers than controls (48.6% vs. 11.1%), and these teens were at fault more frequently than the controls (0.8 vs. 0.4). In keeping with the Weiss and Hechtman (1993) initial report, teens with ADHD were more likely to get speeding tickets (65.7% vs. 33.3%) and got them more often (means = 2.4 vs. 0.6). Two studies in New Zealand using community samples suggest a similarly strong relationship between ADHD and vehicular accident risk (Nada-Raja et al., 1997; Woodward, Fergusson, & Horwood, 2000). Adults diagnosed with ADHD also manifest more unsafe motor vehicle operation and crashes. Six times more adults with ADHD in one study had their licenses suspended (24% vs. 4.0%) than in the control group, and reported having received four times more speeding tickets (means = 4.9 vs. 1.1) than control adults (Murphy & Barkley, 1996). The difference in the frequency of vehicular crashes between the groups was only marginally significant (means = 2.8 vs. 1.8; $p < .06$), however.

Later, in a more thorough examination of driving, Barkley and colleagues (1996a) reported that the group with ADHD reported having had more vehicular crashes than the control group (means = 2.7 vs. 1.6), and that a larger proportion of this group had been involved in more severe crashes (resulting in injuries) than the control participants (60% vs. 17%). Again, speeding citations were overrepresented in these self-reported outcomes of those with ADHD (100% vs. 56%) and occurred more frequently in this group than in the control group (means = 4.9 vs. 1.3).

The most thorough study to date of driving performance among young adults with ADHD (Barkley, Murphy, et al., 2002) used a multimethod, multisource battery of measures. More than twice as many young adults with ADHD as members of the control group (26% vs. 9%) had been involved in three or more vehicular crashes as drivers, and more had been held at fault in three or more such crashes (7% vs. 3%). The group with ADHD had also been involved in more vehicular crashes overall than the control group (means = 1.9 vs. 1.2) and had been held to be at fault in more crashes (means = 1.8 vs. 0.9). The dollar damage caused in their first accidents was estimated to be more than twice as high in the group with ADHD as in the control group (means = $4,221 vs. $1,665). As in the earlier studies, the group with ADHD reported a greater frequency of speeding citations (3.9 vs. 2.4), and a higher percentage had had their licenses suspended than in the control group (22% vs. 5%). The greater frequencies of both speeding citations and license suspensions were corroborated through the official state driving records for these young adults.

A key question concerns the mechanisms that would account for an association of ADHD with driving accidents or proximal behaviors like dangerous driving. The possible mechanisms seem obvious enough: Either distractibility (Farmer & Peterson, 1995; Merrill et al., 2009) or impulsive risk taking (Badger et al., 2008; Garzon, Huang, & Todd, 2008) easily comes to mind. However, with regard to driving problems, Oliver, Nigg, Cassavaugh, and Backs (2012) conducted a small experimental simulation study suggesting that driving errors and accidents in individuals with ADHD were related not to inattention, but to negative emotionality and poor frustration tolerance. This finding was also suggested in another study (Barkley & Fischer, 2010) examining the importance of impulsive emotions as a predictor of various risks and impairments in children with ADHD followed to adulthood.

In any event, these studies leave little doubt that ADHD, or its symptoms of inattention and hyperactive–impulsive behavior (and possibly emotional dysregulation), are associated with a higher risk

for unsafe driving and motor vehicle accidents than in the population without ADHD. This seems to be the case even independently of comorbid CD (Barkley & Cox, 2007), though the potential role of that confounding disorder requires further investigation. In view of the substantial costs that must be associated with such a higher rate of adverse driving outcomes, prevention and intervention efforts to reduce the driving risks among those with ADHD certainly seem needed. Some evidence suggests that ADHD medications may improve driving performance in teens and adults with ADHD (Barkley & Cox, 2007); no research has yet reported on the value of psychsocial treatments for this domain of risk.

Sleep Problems

Many studies over the past four decades or more have suggested an association between ADHD and sleep disturbances (Ball, Tiernan, Janusz, & Furr, 1997; Gruber, Sadeh, & Raviv, 2000; Kaplan, McNichol, Conte, & Moghadam, 1987; Stewart et al., 1966; Trommer, Hoeppner, Rosenberg, Armstrong, & Rothstein, 1988; Wilens, Biederman, & Spencer, 1994). The relationship between sleep and ADHD is quite complex and likely bidirectional, due to the extensive interplay of sleep and diurnal rhythm with basic functions of arousal and attention that are also relevant to ADHD; the numerous shared neurotransmitter systems; and the interplay of behavior and context with sleep readiness and quality. The observational clinical data on ADHD and sleep problems have been reviewed in many places, and interested students can consult Cortese, Faraone, Konofal, and Lecendreux (2009) and other sources (Corkum, Tannock, & Moldofsky, 1998; Spruyt & Gozal, 2011; Yoon, Jain, & Shapiro, 2012). An accessible yet detailed outline of basic mechanisms and research hypotheses and questions that might productively be pursued in ADHD and sleep was recently summarized by a special review panel and published by Owens and colleagues (2013).

In general, those clinical reviews concluded that (1) studies of intrinsic sleep disorder in ADHD (e.g., sleep apnea, parasomnias, restless legs syndrome, circadian rhythm disorder) yield numerous but inconsistent findings; and (2) parent ratings data and actigraphy studies provide fairly convincing evidence that ADHD is often (in perhaps 50% of cases) related to impairments in sleep quality due to sleep-related behavior problems, such as bedtime resistance, sleep-onset difficulties, and trouble with waking in the morning—all of which in turn may exacerbate daytime inattention and overactivity, at least in children (Dahl, 1996; Spruyt & Gozal, 2011) Adults with ADHD are also at substantially higher risk for experiencing disturbed sleep than are control populations; this finding is independent of other psychiatric comorbidities and is not accounted for by ADHD pharmacotherapy (Surman et al., 2009).

More specifically, the sleep-related behavior problems include a longer time to fall asleep, instability of sleep duration, tiredness at awakening, or frequent night waking. For instance, Stein (1999) compared 125 psychiatrically diagnosed children with 83 pediatric outpatient children and found moderate to severe sleep problems in 19% of those with ADHD, 13% of the psychiatric controls, and 6% of pediatric outpatients. These problems could be reduced to three general factors: (1) dyssomnias (bedtime resistance, sleep-onset problems, or difficulty arising); (2) sleep-related involuntary movements (teeth grinding, sleep talking, restless sleep, etc.); and (3) parasomnias (sleepwalking, night wakings, sleep terrors). Dyssomnias were primarily related to comorbid ODD or treatment with stimulant medication, whereas parasomnias were not significantly different from those in the control group. However, involuntary movements were significantly elevated in children with ADHD, combined type.

Within nondisabled populations, quantity of sleep is inversely associated with an increased risk for school behavioral problems (Aronen, Paavonen, Fjallberg, Soinen, & Torronen, 2000), particularly daytime sleepiness and inattention rather than hyperactive–impulsive behavior (Fallone, Acebo, Arnedt, Seifer, & Carskadon, 2001). The direction of effect, then, between ADHD and sleep problems is unclear. It is possible that sleep difficulties increase ADHD symptoms during the daytime, especially for inattention, as the research on typical children implies. Yet some research finds that the sleep problems of children with ADHD are not associated with the severity of their symptoms; this suggests that the disorder, not the impaired sleeping, is what contributes to impaired daytime alertness, inattention, and behavioral problems (Lecendreux, Konofal, Bouvard, Falissard, & Mouren-Simeoni, 2000). Overall, while it is clear that poor sleep can cause inattention, primary sleep disorders do not account for most cases of ADHD. Rather, behavior-related sleep problems may compound problems with ADHD, especially inattention, and in some cases may provide an avenue for intervention.

ASSOCIATED FUNCTIONAL PROBLEMS

Apart from an increased risk for various psychiatric disorders, children and teens with ADHD are also more likely to experience a substantial array of developmental, social, and health risks; these are discussed in this and the next section. Far less is known about the extent to which these correlated problems are evident in those with predominantly inattentive ADHD, particularly the putative subgroup of children who are underactive or sluggish.

Motor Coordination Problems

Problems with motor development have long been associated with ADHD. As a group, as many as 60% of children with ADHD, compared to up to 35% of typical children, may have poor motor coordination or developmental coordination disorder (Barkley, DuPaul, & McMurray, 1990; Hartsough & Lambert, 1985; Kadesjo & Gillberg, 2001; Stewart et al., 1966; Szatmari et al., 1989). Neurological examinations for "soft" signs related to motor coordination and motor overflow movements find children with ADHD to demonstrate more such signs (as well as generally sluggish gross motor movements) than control children, including those with "pure" learning disabilities (Carte et al., 1996; Denckla & Rudel, 1978; Denckla, Rudel, Chapman, & Krieger, 1985; McMahon & Greenberg, 1977). These overflow movements have been interpreted as indicators of delayed development of motor inhibition (Denckla et al., 1985).

Studies using tests of fine motor coordination, such as balance assessment, tests of fine motor gestures, electronic or paper-and-pencil mazes, and pursuit tracking, often find children with ADHD to be less coordinated in these actions (Hoy, Weiss, Minde, & Cohen, 1978; Mariani & Barkley, 1997; McMahon & Greenberg, 1977; Moffitt, 1990; Ullman, Barkley, & Brown, 1978). Simple motor speed, as measured by finger-tapping rate or grooved pegboard tests, does not seem to be as affected in ADHD as is the execution of complex, coordinated sequences of motor movements (Barkley, Murphy, & Kwasnik, 1996b; Breen, 1989; Grodzinsky & Diamond, 1992; Marcotte & Stern, 1997; Mariani & Barkley, 1997; Seidman, Benedict, et al., 1995; Seidman, Biederman, et al., 1995). The bulk of the available evidence therefore supports the existence of deficits in motor control (Harvey et al., 2007), particularly when motor sequences must be performed, in those with ADHD. Such motor difficulties may be part of the family phenotype of ADHD, since they are evident in unaffected siblings as well (Fliers et al., 2010).

Academic Functioning

The vast majority of clinic-referred children with ADHD have difficulties with school performance, most often underproductivity. Such children frequently score lower than typical or control groups of children on standardized achievement tests (Barkley et al., 1990a, 1990b; Fischer, Barkley, Edelbrock, & Smallish, 1990; Hinshaw, 1992, 1994). These differences are likely to be found even in preschool-age children with ADHD (Barkley, Shelton, et al., 2002; Mariani & Barkley, 1997), suggesting that the disorder may take a toll on the acquisition of academic skills and knowledge even before entry into first grade. Indeed, in general population samples, prospective data indicate that early childhood attention problems (defined by Child Behavior Checklist scale scores) prospectively predict adolescent academic failure, even after controlling for intervening IQ and disruptive behavior problems, although ADHD was not formally assessed (Breslau et al., 2010). All of this makes sense, given that some of the executive functions believed to be disrupted by ADHD are also likely to be involved in some forms of academic achievement (e.g., working memory in mental arithmetic or spelling; internalized speech in reading comprehension; verbal fluency in oral narratives and written reports).

A recent review found that 45% of children with ADHD qualified for a diagnosis of a learning disability (DuPaul, Gormley, & Laracy, 2013). Between 19 and 26% of children with ADHD are likely to have any single type of learning disability, conservatively defined as a significant delay in reading, arithmetic, or spelling relative to intelligence and achievement in one of these three areas at or below the 7th percentile (Barkley, 1990). If a learning disability is defined as simply a significant discrepancy between intelligence and achievement, then up to 53% of hyperactive children could be said to have such a disability (Lambert & Sandoval, 1980). Or, if the simple criterion of performance two grades below grade level is used, then as many as 80% of children with ADHD in late childhood (age 11 years) may have learning disorders (Cantwell & Baker, 1992). Studies suggest that the risk for reading disorders among children with ADHD is 16–39%, while that for spelling disorders is 24–27% and for math disorders

is 13–33% (August & Garfinkel, 1990; Barkley, 1990; Capano, Minden, Chen, Schachar, & Ickowicz, 2008; Casey, Rourke, & Del Dotto, 1996; Frick et al., 1991; Semrud-Clikeman et al., 1992).

Although the finding that children with ADHD are more likely to have learning disabilities (Gross-Tsur, Shalev, & Amir, 1991; Tannock & Brown, 2000) might imply a possible genetic link between the two disorders, other research (Doyle, Faraone, DuPre, & Biederman, 2001; Faraone et al., 1993; Gilger, Pennington, & DeFries, 1992) shows that the two sets of disorders are transmitted independently in families. Some subtypes of reading disorders associated with ADHD may have a common genetic etiology (Gilger et al., 1992; Paloyelis, Rijsdijk, Wood, Asherson, & Kuntsi, 2010). This may arise from the finding that early ADHD inattention may predispose children toward certain types of reading problems, whereas early reading problems do not generally give rise to later symptoms of ADHD or are much less likely to do so (Chadwick, Taylor, Taylor, Heptinstall, & Danckaerts, 1999; Grevens, Rijsdijk, Asherson, & Plomin, 2012; Rabiner, Coie, & The Conduct Problems Prevention Research Group, 2000; Velting & Whitehurst, 1997; Wood & Felton, 1994). The picture is less clear for spelling disorders; a common or shared genetic etiology for ADHD and spelling disorder has been shown in a joint analysis of twin samples from London and Colorado (Stevenson, Pennington, Gilger, DeFries, & Gillis, 1993). This may result from the fact that early spelling ability seems to be linked to the integrity of working memory (Mariani & Barkley, 1997; Levy & Hobbes, 1989), which may be impaired in those with ADHD (see the discussion of the theoretical model, above). Writing disorders have not received as much attention in research on ADHD, though handwriting deficits are often found among children with ADHD, particularly those with the combined type (Marcotte & Stern, 1997). Re, Pedron, and Cornoldi (2007) reported three studies that explored the prevalence and nature of these writing problems. It concluded that children with ADHD symptoms scored lower than controls on four qualitative parameters (adequacy, structure, grammar, and lexicon), produced shorter texts, and made more errors. Whether these are distinct from or related to motor or other learning problems is a fruitful area for future study.

Rapport, Scanlan, and Denney (1999) provided some early evidence for a dual-pathway model of the link between ADHD and academic underachievement. Briefly, ADHD may predispose to academic underachievement through its contribution to a greater risk for ODD/CD and conduct problems in the classroom more generally, the net effect of which is an adverse impact on productivity and general school performance. But ADHD is associated with cognitive deficits not only in attention, but in general intelligence (see below) and working memory (see above), all of which may have a direct and adverse impact on academic achievement. Supportive of this view as well are findings that the inattention dimension of ADHD is more closely associated with academic achievement problems than is the hyperactive–impulsive dimension (Faraone, Biederman, Weber, & Russell, 1998; Hynd et al., 1991; Marshall, Hynd, Handwerk, & Hall, 1997; Paloyelis et al., 2010). According to this dual-pathway model, both pathways will require interventions if the marked association of ADHD with school underachievement is to be addressed.

A higher prevalence of speech and language disorders has also been documented in many studies of children with ADHD, typically ranging from 30 to 64% of the samples (Bellani, Moretti, Perlini, & Brambilla, 2011; Gross-Tsur et al., 1991; Hartsough & Lambert, 1985; Szatmari et al., 1989; Taylor et al., 1991). The converse is also true: Children with speech and language disorders have a higher than expected prevalence of ADHD (approximately 30–58%), among other psychiatric disorders (McGrath et al., 2008; see Tannock & Brown, 2000, for a review of comorbidity with ADHD). In children with ADHD, the pragmatic aspects of speeh along with impaired verbal working memory and discourse analysis are the primary difficulties (Bellani et al., 2011).

Reduced Intelligence

For decades, it has been observed that clinic-referred children with ADHD often have lower scores on intelligence tests than control groups used in these same studies, particularly in verbal intelligence (Barkley, Karlsson, & Pollard, 1985; Mariani & Barkley, 1997; McGee, Williams, & Feehan, 1992; Moffitt, 1990; Werry, Elkind, & Reeves, 1987). Deficiencies in both fluid and crystallized intelligence have been noted (Tillman, Bohlin, Sorensen, & Lundervold, 2009). Differences in IQ have also been found between hyperactive boys and their normal siblings (Halperin & Gittelman, 1982; Tarver-Behring, Barkley, & Karlsson, 1985; Welner, Welner, Stewart, Palkes, & Wish, 1977). The differences found in these studies often

range from 7 to 10 standard score points. Studies using both community samples (Hinshaw, Morrison, Carte, & Cornsweet, 1987; McGee et al., 1984; Peterson et al., 2001) and samples of children with behavior problems (Sonuga-Barke, Lamparelli, Stevenson, Thompson, & Henry, 1994) also have found significant negative associations between degree of ADHD and intelligence (r's = –.25–.35). In contrast, associations between ratings of conduct problems and intelligence in children are often much smaller or even nonsignificant, particularly when hyperactive–impulsive behavior is partialed out of the relationship (Hinshaw et al., 1987; Lynam, Moffitt, & Stouthamer-Loeber, 1993; Sonuga-Barke et al., 1994). This implies that the relationship between IQ and ADHD is not likely to be a function of comorbid conduct problems (see Hinshaw, 1992, for a review). Although a portion of the IQ disparity may be attributable to the impact of ADHD on executive functioning (which is also related to IQ), studies suggest that some IQ disparity remains even after statistical controls for executive functioning deficits and may be due to executive attentional deficits (Tillman et al., 2009).

Social Problems

With regard to social impairment, the association between ADHD and peer rejection and neglect is perhaps the most notable. Inattention is more closely associated with peer neglect, and hyperactivity–impulsivity with peer rejection (due to either the intrusiveness or the emotionality and especially aggressiveness linked with the latter dimension of ADHD). The overall association of ADHD with disrupted peer relations was first noted decades ago (Cunningham & Siegel, 1987; Whalen, Henker, Collins, McAuliffe, & Vaux, 1979), but it is becoming increasingly well described (Hoza, 2007; Hoza et al., 2005). This literature highlights the importance of peer effects in overall outcome for ADHD (Hoza et al., 2005; Mikami & Lorenzi, 2011; Mrug et al., 2012), as well as of the interplay across psychosocial domains (e.g., parenting and peer relations; see Hurt, Hoza, & Pelham, 2007; Mikami, Jack, Emeh, & Stephens, 2010). These effects are present in both boys and girls, but girls are understudied, and some indications suggest potential unique patterns of risk and protection in girls (Blachman & Hinshaw, 2002; Mikami & Lorenzi, 2011).

Children with ADHD are less liked by other children, have fewer friends, and are overwhelmingly rejected as a consequence, particularly if they have comorbid conduct problems (Gresham, MacMillan, Bocian, Ward, & Forness, 1998; Hinshaw & Melnick, 1995; Hoza, 2007). Indeed, among children with such comorbidity, up to 70% may be rejected by peers and have no reciprocated friendships by fourth grade (Gresham et al., 1998). These peer relationship problems are the result not only of these children's more active, talkative, and impulsive actions, but also of their greater emotional, facial, tonal, and bodily expressiveness (particularly anger); more limited reciprocity in interactions; use of fewer positive social statements; more limited knowledge of social skills; and more negative physical behavior (Barkley, 2010; Grenell, Glass, & Katz, 1987; Madan-Swain & Zentall, 1990). Those with ODD/CD also prefer more sensation-seeking, fun-seeking, and trouble-seeking activities, which further serve to alienate their nondisabled peers (Hinshaw & Melnick, 1995; Melnick & Hinshaw, 1996). While comorbid ODD or CD is most often associated with even greater peer problems, comorbidity alone does not account for the peer social problems evident in ADHD (Becker, Luebbe, & Langberg, 2012). Furthermore, children with ADHD seem to process social and emotional cues from others in a more limited and error-prone fashion, as if they were not paying as much attention to emotional information provided by othrs. Yet they do not differ in their capacity to understand the emotional expressions of other children (Casey, 1996). However, in those with comorbid ODD/CD, there may be a greater misperception of anger and a greater likelihood of responding with anger and aggression to peers than in typical children (Cadesky, Mota, & Schachar, 2000; Casey, 1996; Matthys, Cuperus, & van Engeland, 1999). Little wonder, then, that children with ADHD perceive themselves as receiving less social support from peers (and teachers) than do typical children (Demaray & Elliot, 2001). The problems with aggression and poor emotion regulation are also evident in the sports behavior of these children with their peers (Johnson & Rosen, 2000). Once more, stimulant medication has been observed to decrease these negative and disruptive behaviors toward teachers (Whalen, Henker, & Dotemoto, 1980) and peers (Cunningham, Siegel, & Offord, 1985; Wallander, Schroeder, Michelli, & Gualtieri, 1987; Whalen et al., 1987), but it may not result in any increase in more prosocial or positive initiatives toward peers (Wallander et al., 1987).

ADHD in children can also have a direct negative influence on familial relationships (Johnston & Mash, 2001; Mash & Johnston, 1990) and on other family

members (Barkley, 2006; Harpin, 2005). These effects may reflect either gene–environment correlations (the parents and children share genes that predispose the children to ADHD and the parents to depression or substance use), or they may also reflect parents' inability to cope with the burden of caring for children with ADHD. This burden may be perceived differently by mothers and fathers, but both appear to experience elevated stress that is only partly attributable to comorbid child defiant/oppositional behavior (Podolski & Nigg, 2001; Theule, Wiener, Rogers, & Marton, 2011).

Parent–child conflict is well appreciated as a complication in ADHD and is an important target for behavioral intervention, as it may contribute to continuing ADHD symptoms (Wells et al., 2000). However, children with ADHD have also reported witnessing more interparental conflict than children without ADHD, which was associated with teacher ratings of ADHD severity (Counts, Nigg, Stawicki, Rappley, & von Eye, 2005)—an effect that may be modulated by child genotype (Martel et al., 2011; Nikolas, Friderici, Waldman, Jernigan, & Nigg, 2010). Still, data from twin studies using behavioral genetic methods indicate that these child reports do not merely reflect child genotype (e.g., temperament), but also environmental effects, such as conflict in the home (Nikolas & Nigg, 2013). These reports indicate that a recursive loop may occur in which ADHD provokes interparental conflict, which in turn exacerbates emotional load and ADHD symptoms in the child. This possibility, and the potential that a subset of children with ADHD are particularly vulnerable, suggests both avenues for intervention and avenues for understanding the underlying etiological process.

ADHD affects the interactions of children with their parents, and hence the manner in which parents may respond to these children (Johnston & Mash, 2001). Those with ADHD are more talkative, negative, and defiant; less compliant and cooperative; more demanding of assistance from others; and less able to play and work independently of their mothers (Danforth et al., 1991; Gomez & Sanson, 1994; Johnston, 1996; Johnston & Mash, 2001). Their mothers are less responsive to the questions of their children, more negative and directive, and less rewarding of their children's behavior (Danforth et al., 1991; Johnston & Mash, 2001). Mothers of children with ADHD have been shown to give both more commands and more rewards to sons with ADHD than to daughters with the disorder (Barkley, 1989a; Befera & Barkley, 1984), but also to be more emotional and acrimonious in their interactions with sons (Buhrmester, Camparo, Christensen, Gonzalez, & Hinshaw, 1992; Taylor et al., 1991). Children and teens with ADHD seem to be nearly as problematic for their fathers as their mothers (Buhrmester et al., 1992; Edwards et al., 2001; Johnston, 1996; Tallmadge & Barkley, 1983). Contrary to what may be seen in typical mother–child interactions, the conflicts between children and teens with ADHD (especially boys) and their mothers may actually increase when fathers join the interactions (Buhrmester et al., 1992; Edwards et al., 2001). Such increased maternal negativity and acrimony toward sons in these interactions has been shown to predict greater noncompliance in classroom and play settings, as well as greater covert stealing away from home, even when the level of the sons' own negativity and parental psychopathology are statistically controlled for in the analyses (Anderson et al., 1994). The negative parent–child interaction patterns also occur in the preschool age group (Cohen, Sullivan, Minde, Novak, & Keens, 1983; DuPaul, McGoey, Eckert, & VanBrakle, 2001), and may be even more negative and stressful (to the parents) in this age range (Mash & Johnston, 1982, 1990) than in later age groups. With increasing age, the degree of conflict in these interactions lessens, but remains deviant from normative levels into later childhood (Barkley, Karlsson, & Pollard, 1985; Mash & Johnston, 1982) and adolescence (Barkley, Anastopoulos, Guevremont, & Fletcher, 1992; Barkley, Fischer, Edelbrock, & Smallish, 1991; Edwards et al., 2001). In families of children with ADHD, negative parent–child interactions in childhood have been observed to be significantly predictive of continuing parent–teen conflicts 8–10 years later in adolescence (Barkley, Fischer, et al., 1991). Few differences are noted between mothers' interactions with their children who have ADHD and their interactions with the siblings of these children (Tarver-Behring et al., 1985).

The presence of comorbid ODD is associated with the highest levels of interaction conflicts between parents and their children and adolescents with ADHD (Barkley, Anastopoulos, et al., 1992; Barkley, Fischer, et al., 1991; Edwards et al., 2001; Johnston, 1996). In a sequential analysis of these parent–teen interaction sequences, investigators have noted that the immediate or first lag in the sequence is most important in determining the behavior of the other member of the dyad (Fletcher, Fischer, Barkley, & Smallish, 1996). That is, the behavior of each member is determined mainly by the immediately preceding behavior of the other member, and not by earlier behaviors of either member in

the chain of interactions. The interactions between the teens with comorbid ADHD/ODD and their parents reflected a strategy best characterized as "tit for tat," in that the type of behavior (positive, neutral, or negative) of each member was most influenced by the same type of behavior emitted immediately preceding it. Mothers of teens with ADHD only and of nondisabled teens were more likely to utilize positive and neutral behaviors regardless of the immediately preceding behavior of their teens; this has been characterized as a "be nice and forgive" strategy, which is thought to be more mature and more socially successful for both parties in the long run (Fletcher et al., 1996). Even so, those with ADHD alone are still found to be deviant from the norm in these interaction patterns, though less so than those with comorbid ADHD/ODD. The presence of comorbid ODD has also been shown to be associated with greater maternal stress and psychopathology, as well as parental marital/couple difficulties (Barkley, Anastopoulos, et al., 1992; Barkley, Fischer, et al., 1991; Johnston & Mash, 2001; Theule et al., 2011).

These interaction conflicts in families of children with ADHD are not limited to parent–child interactions. Increased conflicts have been observed between children with ADHD and their siblings, relative to typical child–sibling dyads (Mash & Johnston, 1983b; Taylor et al., 1991). Research on the larger domain of family functioning has shown that families of children with ADHD experience more parenting stress and decreased sense of parenting competence (Johnston & Mash, 2001; Mash & Johnston, 1990; Theule et al., 2011); increased alcohol consumption in parents (Cunningham, Benness, & Siegel, 1988; Pelham & Lang, 1993); decreased extended family contacts (Cunningham et al., 1988); and increased marital/couple conflict, separations, and divorce, as well as maternal depression (Barkley, Fischer, et al., 1990; Befera & Barkley, 1984; Cunningham et al., 1988; Johnston & Mash, 2001; Lahey et al., 1988; Taylor et al., 1991). Again, the comorbid association of ADHD with ODD or CD is linked to even greater degrees of parental psychopathology, marital/couple discord, and divorce than is ADHD only (Barkley, Fischer, et al., 1990, 1991; Lahey et al., 1988; Taylor et al., 1991). Interestingly, Pelham and Lang (1993) have shown that the increased alcohol consumption in these parents is in part a direct function of their stressful interactions with their children with ADHD. Those findings were recently replicated and extended in a larger study by showing that the increase in alcohol consumption was partly mediated by parental stress reactivity (Kashdan, Adams, Kleiman, Pelham, & Lang, 2013).

Research has demonstrated that the primary direction of effects within these interactions is from child to parent (Danforth et al., 1991; Johnston & Mash, 2001; Mash & Johnston, 1990), rather than the reverse. That is, much of the disturbance in the interaction seems to stem from the effects of the child's excessive, impulsive, unruly, noncompliant, and emotional behavior on the parent, rather than from the effects of the parent's behavior on the child. This was documented primarily through studies that evaluated the effects of stimulant medication on the behavior of such children and their interaction patterns with their mothers. Such research found that medication improves the compliance of those with ADHD and reduces their negative, talkative, and generally excessive behavior, so that their parents reduce their levels of directive and negative behavior as well (Barkley & Cunningham, 1979a; Barkley, Karlsson, Pollard, & Murphy, 1985; Danforth et al., 1991; Humphries, Kinsbourne, & Swanson, 1978). These effects of medication are noted even in preschool-age children with ADHD (Barkley, 1988), but also in those in late childhood (Barkley, Karlsson, Pollard, & Murphy, 1985), as well as in children of both sexes (Barkley, 1989a).

Nonetheless, parental ADHD may have difficult-to-predict effects in relation to child adjustment in children with ADHD. Because ADHD is familial, many children with ADHD have at least one parent who also has ADHD. ADHD in a parent may contribute to breakdowns in parenting effectiveness that may make it more difficult for that parent to handle that particularly challenging child (Johnston, Mash, Miller, & Ninowski, 2012). Alternatively, the parent with ADHD may more easily empathize with the child who has ADHD, reducing conflict between them. More research in this regard will be of interest.

Besides a general reduction in the negative, disruptive, and conflictual interaction patterns between children with ADHD and their parents as a result of stimulant medication, general family functioning also seems to improve when these children are treated with stimulant medication (Schachar, Taylor, Weiselberg, Thorley, & Rutter, 1987). None of this is meant to suggest that parental reactions to disruptive child behavior; parental skill and competence in child management and daily rearing; and parental psychological impairment are unimportant influences on children with ADHD. Evidence certainly shows that parental man-

agement, child monitoring, parental antisocial activity, maternal depression, father absence, and other parent and family factors are exceptionally important in the development of ODD, CD, major depression, and other disorders likely to be comorbid with ADHD (Johnson, Cohen, Kasen, Smailes, & Brook, 2001; Johnston & Mash, 2001; Patterson et al., 2000; Pfiffner, McBurnett, & Rathouz, 2001). But it must be emphasized, as the behavioral genetic studies described below strongly attest, that these are not the origins of the impulsive, hyperactive, and inattentive behaviors or the related deficits in executive functioning and self-regulation.

ETIOLOGY AND PATHOPHYSIOLOGY

ADHD falls into a group of disorders known as "complex disease," meaning that etiology is multifactorial and probabilistic. An important goal is to identify particular etiologies that may function as risk factors and thus may be used to predict clinical outcome, as well as to open the door for prevention. Etiological factors can include the interplay of genetic liability and environmental potentiators. Pathophysiology then concerns the particular neurobiological processes that may be involved in development and enable us to eventually place more precise biological markers on ADHD. We thus consider first neurobiological factors, then genetic factors.

Neurobiological Factors

Various neurological etiologies have been proposed for ADHD. Brain damage was initially proposed as a chief cause of ADHD symptoms (see "Historical Context," above), whether it occurred as a result of known brain infections, trauma, or other injuries or complications occurring during pregnancy or at the time of delivery. Several studies show that brain damage, particularly hypoxic/anoxic types of insults, is associated with greater attention deficits and hyperactivity (Cruickshank, Eliason, & Merrifield, 1988; O'Dougherty, Nuechterlein, & Drew, 1984). ADHD symptoms also occur more often in children with seizure disorders (Holdsworth & Whitmore, 1974) that are clearly related to underlying neurological malfunction. However, most children with ADHD have no history of significant brain injuries or seizure disorders, and so brain damage is unlikely to account for the majority of children with ADHD (Rutter, 1977).

Throughout the past 100 years, investigators have repeatedly noted the similarities between symptoms of ADHD and those produced by lesions or injuries to the frontal lobes more generally and the prefrontal cortex specifically (Barkley, 1997a; Benton, 1991; Heilman, Voeller, & Nadeau, 1991; Levin, 1938; Mattes, 1980). Both children and adults suffering injuries to the prefrontal region demonstrate deficits in sustained attention, inhibition, regulation of emotion and motivation, and the capacity to organize behavior across time (Fuster, 1997; Stuss & Benson, 1986). In the past 20 years, this discussion has been transformed by dramatic advances both in neuroimaging technology and in appreciation of the complex, interdependent, and nonlinear nature of neural development.

Early research in the 1960s and 1970s focused on psychophysiological measures of nervous system (central and autonomic) electrical activity, variously measured (electroencephalograms [EEGs], galvanic skin responses, heart rate deceleration, etc.). These studies were inconsistent in demonstrating group differences between children with ADHD and control children in resting arousal. But where differences from typical children were found, they were consistently in the direction of diminished reactivity to stimulation, or arousability, in those with ADHD (see Hastings & Barkley, 1978, for a review). Later research continued to demonstrate differences in skin conductance and heart rate parameters in response to stimulation in those with ADHD (Borger & van der Meere, 2000), which may distinguish them from children with CD or those with comorbid ADHD and CD (Beauchaine, Katkin, Strassberg, & Snarr, 2001; Herpertz et al., 2001).

Far more consistent have been the results of quantitative EEG (qEEG) and event-related potential (ERP) measures, sometimes taken in conjunction with vigilance tests (Frank, Lazar, & Seiden, 1992; Klorman, 1992; Klorman, Salzman, & Borgstedt, 1988). Although results have varied substantially across these studies (see Loo & Makieg, 2012, for a review), the most consistent pattern for qEEG research is increased slow-wave or theta activity (particularly in the frontal lobe) and excess beta activity, all potentially indicative of a pattern of underarousal and underreactivity in ADHD (Loo & Makieg, 2012; Monastra, Lubar, & Linden, 2001). Some of these qEEG differences may be linked to the DRD4 gene polymorphisms known to increase risk for the disorder (Loo et al., 2010). Children with ADHD also have been found to have smaller amplitudes in the late positive and negative components

of their ERPs. These late components are believed to be functions of the prefrontal regions of the brain, are related to poorer performances on inhibition and vigilance tests, and are improved by stimulant medication and motivational manipulations (Groom et al., 2010; Johnstone, Barry, & Anderson, 2001; Johnstone, Barry, Markovska, Dimoska, & Clarke, 2009; Kuperman, Johnson, Arndt, Lindgren, & Wolraich, 1996; Pliszka, Liotti, & Woldorff, 2000). Thus psychophysiological abnormalities related to sustained attention and inhibition demonstrate an underresponsiveness of children with ADHD to stimulation that is improved or even corrected by stimulant medication.

Several studies have also examined cerebral blood flow using single-photon emission computed tomography (SPECT) in children with ADHD and typical children (for reviews, see Hendren, De Backer, & Pandina, 2000; Tannock, 1998). They have consistently shown decreased blood flow to the prefrontal regions (most recently in the right frontal area), and to pathways connecting these regions with the limbic system via the striatum and specifically its anterior region known as the caudate, and with the cerebellum (Gustafsson, Thernlund, Ryding, Rosen, & Cederblad, 2000; Yeh et al., 2012). Degree of blood flow in the right frontal region has been correlated with behavioral severity of the disorder, while that in more posterior regions and the cerebellum seems related to degree of motor impairment (Gustafsson et al., 2000).

More than a decade ago, a radioactive chemical ligand known as [I^{123}]Altropane was developed that binds specifically to the dopamine transporter protein in the striatum of the brain, and thus can be used to indicate level of dopamine transporter activity within this region. Following intravenous injection of the ligand, SPECT is used to detect the binding activity of Altropane in the striatum. The dopamine transporter is responsible for the reuptake of extracellular dopamine from the synaptic cleft after neuronal release. Several pilot studies found that adults with ADHD had significantly increased binding potential of Altropane and thus greater dopamine transporter activity (Dougherty et al., 1999; Krause, Dresel, Krause, Kung, & Tatsch, 2000). These findings are interesting because research suggests that the drug methylphenidate, which is often used to treat ADHD, has a substantial effect on activity in this brain region and may produce its therapeutic effect by slowing down this dopamine transporter activity (Krause et al., 2000; Volkow et al., 2001).

Studies using positron emission tomography (PET) to assess cerebral glucose metabolism have found diminished metabolism in adults with ADHD, particularly in the frontal region (Schweitzer et al., 2000; Zametkin et al., 1990), and in adolescent females with ADHD (Ernst et al., 1994), but have proven negative in adolescent males with ADHD (Zametkin et al., 1993). An attempt to replicate the finding in adolescent females with ADHD in younger female children with ADHD failed to find such diminished metabolism (Ernst, Cohen, Liebenauer, Jons, & Zametkin, 1997). Such studies are plagued by their exceptionally small sample sizes, which result in very low power to detect group differences and considerable unreliability in replicating previous findings. However, significant correlations have been noted between diminished metabolic activity in the anterior frontal region and severity of ADHD symptoms in adolescents with ADHD (Zametkin et al., 1993). Also, using a radioactive tracer that indicates dopamine activity, Ernst and colleagues (1999) found abnormal dopamine activity in the right midbrain region of children with ADHD, and discovered that severity of symptoms was correlated with the degree of this abnormality. These demonstrations of an association between the metabolic activity of certain brain regions on the one hand, and symptoms of ADHD and associated executive deficits on the other, are critical to proving a connection between the findings pertaining to brain activation and the behaviors constituting ADHD.

MRI (both functional and structural) of ADHD, however, now constitutes the primary avenue of study. This research has been reviewed in detail in meta-analyses, most recently by Cortese and colleagues (2012). By the late 1990s, the basic outlines of circuitry in ADHD were becoming clear. Functional MRI activity in various brain regions revealed that children with ADHD had altered patterns of activation during attention and inhibition tasks, particularly in the right prefrontal region, the basal ganglia (striatum and putamen), and the cerebellum (Cortese et al., 2012; Rubia et al., 1999; Teicher et al., 2000).

Significant progress has been reported by a longitudinal brain imaging study established at the intramural child psychiatry branch at the National Institutes of Health in the 1990s, which has yielded several interesting reports and reviews in the past decade (Castellanos et al., 2002; Giedd, Blumenthal, Molloy, & Castellanos, 2001; Krain & Castellanos, 2006; Shaw et al., 2007; Shaw, Lerch, et al., 2006). This research,

which has focused only on brain structure, initially revealed that alterations in structural volume in ADHD were present early in life, were not explained by medication treatment, and appeared to be nonprogressive. These findings suggested that early life insult or genetic influences were primarly responsible for observed alterations in brain structure in ADHD. More recently, a series of papers from this study (see Shaw, Lerch, et al., 2006) has examined cortical thickness measures. These appear to show a more dynamic pattern, with altered or delayed trajectory of cortical mantle thickening and then normative thinning during adolescent development. This finding highlights that despite some early alterations, the trajectory of development of the brain and the timing of developmental events will be extremely important to clarify in the coming decade of research on ADHD.

That specific regulatory brain systems are involved in ADHD is now supported by dozens of studies (Casey et al., 2007; Cubillo et al., 2010; Epstein et al., 2009; Gatzke-Kopp et al., 2009; Rubia, 2011; Rubia et al., 2010; Stanley et al., 2008) and, decisively, by comprehensive meta-analyses (Bush, 2010; Dickstein, Bannon, Castellanos, & Milham, 2006). First, ADHD involves frontal–subcortical (frontal–limbic/frontal–striatal) circuits, important for behavioral and emotional regulation and impulse control (including dorsolateral and ventromedial prefrontal cortex, dorsal anterior cingulate cortex, amygdala, and regions of striatum, as well as thalamus; Dickstein et al., 2006; Nigg & Casey, 2005). These findings are supported by diffusion tensor imaging studies as well, where meta-analysis shows widespread alterations in white matter (van Ewijk, Heslenfeld, Zwiers, Buitelaar, & Oosterlaan, 2012) but also anterior corona radiata/longitudinal fasciculus and internal capsule, consistent with our circuit model.

Second, as shown in two separate meta-analyses (Cortese et al., 2012), ADHD involves abnormality in nodes in frontal–parietal–subcortical circuits (the canonical ventral attention stream but also the dorsal stream, including dorsolateral prefrontal cortex and inferior parietal lobule). Third, a circuit that was little discussed until recently, called the "default mode network," appears to operate abnormally in ADHD. The default mode circuit is a network of structures that tends to be active at rest (e.g., when the mind is wandering or not engaged in a task). This circuit tends to shut off during task engagement—but not as well in ADHD. It includes medial and lateral parietal cortex, medial prefrontal cortex, and precuneus/ posterior cingulate cortex (or retrosplenial cortex) (Cortese et al., 2012). The method used to assess these circuits—resting-state functional connectivity—assesses spontaneous correlations of activity throughout the brain during rest, when the brain is actually very active. While many methodological questions remain about this newer method of brain assessment, the findings are intriguing and likely to continue to inform brain development in ADHD.

These brain alterations involve both structure and function—and, increasingly, connectivity among regions. The various brain regions and circuits often implicated in ADHD are illustrated in Figure 2.3. It illustrates three fundamental types of circuits that are relevant. The prefrontal cortex is important for behavioral control and regulation, but as outlined by Casey, Nigg, and Durston (2007) and Nigg and Casey (2005), subcortical and posterior brain regions are important in signaling the control systems to engage. Frontal–parietal circuits are involved in attentional capture, including a dorsal and a ventral attention circuit involved in attentional allocation and in attentional capture by new information, respectively. The frontal–thalamic–basal ganglia loop actually implicates multiple parallel neural circuits that are differentially involved in regulating motor response and emotional response. Cerebellar–frontal loops are involved in helping to learn temporal associations of events and their consequences.

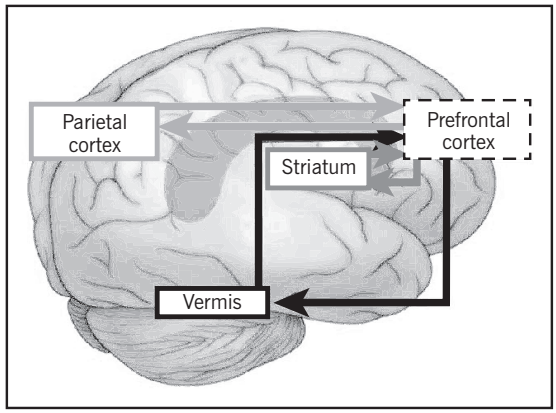

FIGURE 2.3. Conceptual brain circuits involved in ADHD. From Casey, Nigg, and Durston (2007). Copyright 2007 by Lippincott Williams & Wilkins. Reprinted by permission.

Again, the demonstrated linkage of brain structure and function with psychological measures of ADHD symptoms and executive deficits is exceptionally important in such research, to permit causal inferences to be made about the role of these brain abnormalities in the cognitive and behavioral abnormalities constituting ADHD. However, the effects are still not large or specific enough to permit the identification of individual cases. Much work remains to be done to render this work clinically applicable in terms of selecting individual children with particular brain alterations related to their individual cases of ADHD.

Neurotransmitter Associations with ADHD

Possible neurotransmitter dysfunction or imbalances, especially in dopamine pathways (Tripp & Wickens, 2008) have been proposed in ADHD for quite some time. (See Pliszka, McCracken, & Maas, 1996, for an early review; for an alternative view, see Arnsten, 2001; more recent formulations have been discussed in the "Theoretical Considerations" section of this chapter.) Initially, these ideas rested chiefly on the responses of children with ADHD to differing drugs.

Children with ADHD tend to respond dramatically to stimulants, most of which act by changing availability of dopamine at the synapse via various mechanisms, and by producing some effects on the noradrenergic pathways as well (Connor, 2006). The mechanism of action in ADHD is dynamic in that there is acute increase of dopamine availability at the synapse, but this is accompanied by changes over time in receptor density in some brain areas. Nonetheless, it is clear that increased dopamine availability at the synapse, particularly in circuitry related to motivation and incentive response, is one part of the effect (for recent findings and expert discussions, see Swanson, Baler, & Volkow, 2011; Volkow et al., 2012). These children also respond well to noradrenergic agonists, providing further support for a possible noradrenergic basis to ADHD (Arnsten, 2001). Consequently, it seemed sensible to hypothesize that these two neurotransmitters might be involved in the disorder. The finding that nondisabled children show a positive (albeit lesser) response to stimulants (Rapoport et al., 1978), however, partially undermines this logic. Other, more direct evidence comes from studies of cerebrospinal fluid in children with ADHD and typical children, which indicate decreased brain dopamine in the children with ADHD (Raskin, Shaywitz, Shaywitz, Anderson & Cohen, 1984). Similarly, other studies have used blood and urinary metabolites of brain neurotransmitters to infer deficiencies in ADHD, largely related to dopamine regulation. Early studies of this sort proved conflicting in their results (Shaywitz, Shaywitz, Cohen, & Young, 1983; Shaywitz et al., 1986; Zametkin & Rapoport, 1986). A subsequent study continued to find support for reduced noradrenergic activity in ADHD, as inferred from significantly lower levels of a metabolite of this neurotransmitter (Halperin et al., 1997).

Environmental and Genetic Factors

Genetic Factors

Family studies established long ago that ADHD runs in families, with at least a two- to fourfold increased risk among first-degree relatives (Mick & Faraone, 2009). How much of this familial similarity is due to genes versus common family experiences? Over a dozen behavioral genetic (twin and/or adoption) studies of ADHD have established that in parent ratings, substantial portions of liability are carried by genetic variation; the heritability coefficient, averaged across many studies, exceeds .80 (Boomsma, Cacioppo, Muthen, Asparouhov, & Clark, 2007; Grant et al., 2007). Heritability estimates are somewhat lower, however, when teacher ratings are examined, although the heritability of a latent variable for shared parent and teacher agreement was .78 in a large Dutch sample (Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005). Relatively few studies have examined twin concordance of ADHD diagnoses derived from full clinical evaluation or from the combination of parent and teacher input on symptoms and impairment.

The variation in results for teacher versus parent ratings raises questions of rater bias (also known as "contrast bias") as an influence on heritability estimates. Contrast bias (i.e., parents' emphasizing differences more in dizygotic than in monozygotic twins) is known to inflate heritability estimates of activity level in preschoolers. Such effects in ADHD ratings appear to depend on what rating scale is used. Rietveld, Hudziak, Bartels, van Beijsterveldt, and Boomsma (2004) reported on a longitudinal study of a large sample of twins in Europe, with maternal Child Behavior Checklist ratings at four age points (3, 7, 10, and 12 years). Even with rater contrast effects controlled, heritability

was above .70 at each age. Simonoff and colleagues (1998) confirmed maternal contrast effects but also noted biases in teacher ratings due to twin confusion (also known as "correlated errors"), especially for monozygotic twins. In other words, many twins have the same teacher, and teachers have more difficulty keeping monozygotic twins straight in their minds. When these effects are accounted for, heritability was in the range of .60–.70.

In sum, the heritability of ADHD is likely to be about .70, which is substantial for a psychological trait and greater than that for many other traits or disorders. Nonshared environmental effects account for the remainder of variance in ADHD liability. In response to these findings, researchers aggressively pursued molecular genetic studies during the period from 2000 to 2010.

The most common approach to studying molecular correlates in ADHD initially was to look at candidate genes—that is, selected markers on genes believed for theoretical reasons to be of interest, such as dopamine receptor genes. A meta-analysis of that literature indicated that six genes have common markers that had been reliably associated with ADHD to that point: dopamine transporter (DAT1), dopamine D4 and D5 receptors (DRD4, DRD5), serotonin transporter (5-HTTPLR), serotonin 1B receptor gene (HTR1B), and synaptosomal-associated protein of molecular weight 25 kDa (SNAP25) (Gizer et al., 2008). However, ongoing larger studies will likely identify new associations.

A second approach is to conduct genome-wide scans. With this approach, searches are conducted across hundreds of thousands of common markers (called single-nucleotide repeats or polymorphisms). Somewhat to the surprise and disappointment of many scientists, genome-wide scans have failed to identify important new genes in ADHD (Maliakkal et al., 1992). In part, such failures have occurred because a very large number of statistical tests are required (hundreds of thousands), resulting in low statistical power. Yet pending studies appear likely to identify genome-wide significant markers in psychiatric illness. Furthermore, the studies have identified additional candidates that warrant follow-up, including one that is under a genome-wide significant linkage peak in a meta-analysis, the cadhedrin coding gene known as cadhedrin 13 (CDH13) (Lasky-Su et al., 2008). This gene is expressed in nicotinic receptors and neurite outgrowth (Canino & Alegria, 2008).

A third approach is to organize common gene variants into their chemical and physiological groupings, called "pathways." This approach tests for significant association with an over- or underexpressed pathway and thus has more power than searches for individual markers have. To date, only two studies have attempted this approach with ADHD, and both used a limited approach of examining enrichment of a subset of only already known pathways (the existing catalogues of biological gene pathways as well as gene sets are notably varied as well as incomplete). Still, results were intriguing. Poelmans, Pauls, Buitelaar, and Franke (2011) identified a coherent network related to nicotinic receptors (already one of the biochemical theories of ADHD) and related to neural growth (relevant to newer theories of neurodevelopmental delay). Stergiakouli and colleagues (2012) also identified relevant biological pathways, most interestingly in those metabolic systems related to central nervous system development and choleresterol metabolism (essential for neural development). Once again, the findings, although representing only a first look at this type of approach and likely to be updated in coming years, provoke new ideas about pathophysiology. It is likely that more gene-pathway-based approaches will be fruitful in the future.

A fourth approach, which has been somewhat successful in research on schizophrenia and ASD, is to examine rare structural variants, many of which are copy number variants (meaning that the only difference in such a variant is that a given nucleotide sequence is repeated too many times). This can be accomplished by reanalyzing data from genome-wide scans. For example, one of the first attempts at this method found evidence of a rare copy number variation at a locus related to ADHD on chromosome 15 at q13.3 occurring in a little under 1% of the population, which doubles the risk of ADHD (Williams et al., 2012). Another study using a similar approach concluded that the PARK2 gene (a gene associated with Alzheimer disease) has a rare variant occurring in < 1% of the population that is overrepresented in ADHD (Jarick et al., 2014). More studies of this type are likely to emerge.

New variants can be discovered by sequencing exomal regions of the genome (nonsynonymous variants) or by sequencing the entire genome. These types of studies are now underway in ADHD on a large scale and are likely to yield new discoveries in the coming decade. At this writing, an international consortium has assembled 15,000 samples of children with ADHD

and control children for an analysis of nonsynonymous (functional) variants, most of which are relatively rare in the population; the researchers are using a chip array, but not yet doing sequencing. Sequencing is just getting underway, but is expected to identify some rare causal variants, similar to what is already occurring in ASD research.

In short, the molecular genetics of ADHD remains a vibrant, exciting area of research, despite some surprising and disappointingly small results to date. The problem of the "missing heritability" in ADHD, as in all of psychiatry, remains an interesting problem. Recent work suggests that when we consider polygenetic effects, that there is not so much missing heritability after all. However, a key issue is likely to remain gene × environment interaction (G×E) and/or epigenetic effects.

Gene × Environment Interaction

]In the past decade, studies of G×E have become the norm in psychiatric research. Most of these studies examine one or two selected genetic markers (candidates) in relation to selected measures of the environment. The hazards in such studies are many. In particular, (1) the environmental measure may itself be influenced by variation in unmeasured genes; and (2) if variables are not properly scaled, artifactual or false-positive effects are easily found. Nonetheless, initial efforts in this area have been interesting. A recent meta-analysis (Nigg, Nikolas, & Burt, 2010) indicated reliable and consistent interactions of psychosocial distress measures and genotype, particularly for DAT1 and 5-HTTLPR, in predicting ADHD. Although these effects remain reliant on a few small studies and could still be overturned, more work on G×E in ADHD is likely to be of considerable interest in coming years.

Furthermore, recent years have seen exciting developments in "epigenetics"—that is, the ways in which experience can alter the genome and thus the phenotype, sometimes dramatically. This occurs through multiple mechanisms; the most commonly studied to date is DNA methylation (modification of chromatin, the material in which DNA is "housed"), which can alter gene expression in an ongoing manner. That is, the expression of much of human variation may not depend only on DNA structure, but on the regulatory markings that control whether and how a gene is expressed.

These two insights (the importance of G×E and the importance of epigenetic effects) have sparked a renaissance in studies of environmental contributions to ADHD (as well as several other psychiatric conditions).

Environmental Risks and Triggers

When G×E and epigenetic mechanisms are recognized, many possible environmental contributors to the etiology of ADHD emerge as potentially important. A fruitful way to think about the etiology of ADHD is to consider structural DNA (the part that, as far as we know, cannot be changed except by mutations) as conveying liability or susceptibility to ADHD. Experiences then activate the condition, either by causing direct changes in the brain or physiology, or via epigenetic markings that change gene expression. This model suggests that a given environmental risk will not affect all children; some are "immune" to the effect, but other children will be susceptible and develop ADHD in the presence of this risk.

G×E empirical studies tend to support such possibilities. For example, it is known that (1) neurotoxic pesticide clearance rates from the body depend on genotype (Engel et al., 2011); (2) blood lead levels are modulated by iron uptake, which in turn is controlled by genotype; and (3) responses to dietary additives may be modulated by genotype (Stevenson et al., 2010). It also appears from neuroimaging studies of discordant identical twins (i.e., cases in which one twin has ADHD and one does not) that major changes in the brain associated with ADHD are not accounted for genetically (Castellanos et al., 2002). Thus it appears likely that a susceptibility–plasticity model will ultimately work best for ADHD (and probably for other kinds of psychopathology and complex disease generally), rather than a genetic main-effect model.

As for specific environments, several are notable. First, commentators have suggested that inadequate schooling, rapid societal tempo, and family stress are contributing to an alleged increase in ADHD incidence. Many of these sociological ideas are interesting but untested (or untestable), and some proposed factors (e.g., schooling) occur too late in development to account for ADHD onset.

Regarding other potential environmental potentiates of genetic liability, both pre- and postnatal biological context may be especially important. For example, low birth weight (< 2,500 grams) is a specific risk factor for inattention, hyperactivity, and certain learning and motor problems, but not other behavioral or emotional problems at age 6 (Willcutt, 2012). However, low birth

weight is itself multiply determined by factors such as maternal health and nutrition, maternal smoking, maternal weight, low SES, stress, and other factors, making identification of specific biological mechanisms difficult.

Some studies have not found a greater incidence of pregnancy or birth complications in children with ADHD compared to normal children (Barkley, DuPaul, & McMurray, 1990), whereas others have found a slightly higher prevalence of unusually short or long labor, fetal distress, low forceps delivery, and toxemia or eclampsia (Hartsough & Lambert, 1985; Minde, Webb, & Sykes, 1968). Nevertheless, though children with ADHD may not experience greater pregnancy complications, prematurity, or lower birth weight as a group, children who are born prematurely or who have markedly lower birth weights are at high risk for later hyperactivity or ADHD (Breslau et al., 1996; Schothorst & van Engeland, 1996; Sykes et al., 1997; Szatmari, Saigal, Rosenbaum, & Campbell, 1993). It is not merely low birth weight that seems to pose the risk for symptoms of ADHD or the disorder itself (among other psychiatric disorders), but the extent of white matter abnormalities due to birth injuries, such as parenchymal lesions and/or ventricular enlargement (Whittaker et al., 1997). These findings suggest that although certain pregnancy complications may not be the cause of most cases of ADHD, some cases may arise from such complications, especially prematurity associated with minor bleeding in the brain.

Several studies suggest that mothers of children with ADHD are younger when they conceive these children than are mothers of control children, and that such pregnancies may have a greater risk of adversity (Denson, Nanson, & McWatters, 1975; Hartsough & Lambert, 1985; Minde et al., 1968). Since pregnancy complications are more likely to occur among young mothers, mothers of children with ADHD may have a higher risk for such complications, which may act neurologically to predispose their children toward ADHD. However, the complications that have been noted to date are rather mild and hardly represent compelling evidence of pre- or perinatal brain damage as a cause of ADHD. Some epidemiological studies have generally found a significant association between pre- or perinatal adversity (apart from prematurity as noted above) and symptoms of ADHD (Froehlich et al., 2011; Pineda et al., 2007). But some of these associations dissipate once other factors are taken into account, such as maternal smoking (see below) and socioeconomic disadvantage, both of which may predispose offspring to perinatal adversity and hyperactivity (Goodman & Stevenson, 1989; Werner et al., 1971).

One study found that the season of a child's birth was significantly associated with risk for ADHD, at least among those subgroups of children who either also had a learning disability or did not have any psychiatric comorbidity (Mick, Biederman, & Faraone, 1996). Birth in September was overrepresented in this subgroup of children with ADHD. The authors conjecture that the season of birth may serve as a proxy for the timing of seasonally mediated viral infections to which these mothers and their fetuses may have been exposed, and that such infections may account for approximately 10% of cases of ADHD.

On the other hand, an extensive literature indicates that some prenatal teratogens increase risk of ADHD. For example, alcohol exposure, at least for women in the United States at moderate levels of drinking (Huo et al., 1992), seems to increase risk of offspring ADHD in some studies; however, other researchers suggest that the link is due to confounding by co-occurring social adversity and smoking (Rodriguez et al., 2009). Fetal alcohol exposure may result in a somewhat distinct neuropsychological profile from that of typical ADHD, with particular problems in visual attention and mathematics. Prospective population studies implicate household and outdoor pesticide exposures during critical periods in pregnancy as predictive of ADHD (Goldman et al., 1997; Sagiv et al., 2010). A crucial challenge is to determine whether such correlates, even though they emerge in prospective population based studies, are causal. Although G×E as well as gene–environment correlation can mask environmental effects, they can also mask genetic effects. Teratogens and toxins could be proxies for genetic risk because of gene–environment correlation.

Although experimental proof among humans is difficult to obtain, it is not impossible particularly through the avenue of clinical trials. A meta-analysis of randomized experimental data concluded that dietary factors provide a clinically meaningful causal influence on ADHD (Nigg, Lewis, Edinger, & Falk, 2012). In contrast, two clever family designs—one using surrogate mothers who were related and unrelated to their offspring, and one using siblings who differed in whether their mother smoked during pregnancy—both concluded that causal effects of prenatal smoking on ADHD were likely to be far smaller than previously believed (D'Onofrio et al., 2008; Thapar et al., 2009).

It is also possible that prenatal nicotine exposure is linked more specifically with conduct problems than with ADHD (e.g., Gatzke-Kopp et al., 2009).

It is unclear into which category neurotoxicants will fall. However, because they are fairly universally distributed in the population, exposure to them, unlike maternal smoking, is unlikely to be a proxy for genetic risk. In addition to early household pesticide exposure, particularly well studied are effects of lead exposure. It has been known for centuries that lead is neurotoxic, and for decades that lead at sufficiently high exposures can cause hyperactivity and other health problems. However, more unexpected in the past decade has been the discovery that even at background-level exposure—which is near-universal in the U.S. population (about 1 ug/dL of blood)—blood lead level is correlated with ADHD symptoms (Nigg et al., 2008; Nigg, Nikolas, Knottnerus, Cavanagh, & Friderici, 2010; Roa et al., 1994; Willcutt et al., 2012). The link between lead levels and ADHD appears to be as reliable as, and of a similar magnitude to, that shown between lead and reduced intelligence (Goodlad, Marcus, & Fulton, 2013). It will be extremely difficult to prove causal effects, but from a precautionary point of view these findings are of significant public health concern because the levels of lead being studied remain common in the United States and are epidemic in many nations around the world.

Many other experiential factors have been hypothesized to influence ADHD, from general sociological claims such as "faster pace of life" to more testable effects of early electronic media exposure on brain development. Although no conclusive evidence has been reported for those various ideas, it remains possible that important discoveries will emerge regarding experiential triggers.

Summary

It should be evident from the research reviewed here that ADHD arises from multiple factors, and that neurological and genetic factors are substantial contributors. Like Taylor (1999), Nigg and Casey (2005), Sonuga-Barke (2005), and others, we envision ADHD as having a heterogeneous etiology, with various developmental pathways leading to this behavioral syndrome. These various pathways, however, may give rise to the disorder through disturbances in a final common pathway in the nervous system. That pathway appears to be the integrity of the prefrontal cortical–striatal–cerebellar network. It now appears that hereditary factors play the largest role in the occurrence of ADHD symptoms in children. It may be that what is transmitted genetically is a tendency toward a smaller and less active prefrontal–striatal–cerebellar network. The condition can also be caused or exacerbated by pregnancy complications, exposure to toxins, or neurological disease. Social factors alone cannot be supported as causal of this disorder, but such factors may exacerbate or attenuate the condition, contribute to its persistence, increase the degree of impairment in major life activities, and (most likely) contribute to the forms of comorbid disorders associated with ADHD. Cases of ADHD can also arise without a genetic predisposition to the disorder, provided that children are exposed to significant disruption of or injury to this final common neurological pathway, but this would seem to account for only a small minority of children with ADHD.

In general, then, research conducted since the second edition of this text was published has further strengthened the evidence for genetic and developmental neurological factors as likely causes of this disorder, while greatly reducing the support for purely genetic or purely environmental factors as having a role in most instances of ADHD. Instead, it is likely that a small percentage of cases will be attributable to rare genetic mutations; another small percentage to severe environmental deprivation; and the main group of cases to various combinations of genetic susceptibility and early environmental challenge or insult, perhaps mediated by epigenetic mechanisms.

FUTURE DIRECTIONS

A number of the issues raised in this chapter point the way to potentially fruitful research. The theoretical models discussed above suggest the continued need to examine multiple mechanistic models in conjunction (e.g., temporal information processing and cognition); to expand the routine investigation of ADHD phenomonology to study of emotion and emotion regulation; to consider developmental theory; and to be constrained by what is known about neural development and neurobiology. Furthermore, there is clearly much to learn about G×E effects and the epigenetics of ADHD.

Certainly, the diagnostic criteria developed to date, even though the most rigorous and empirical ever provided, still have important limitations. The fact that such criteria are not theory-driven and developmentally referenced, despite being empirically derived, risks cre-

ating several difficulties for understanding the disorder and clinically applying these criteria. The criteria probably do not map cleanly onto neurobiology, but rather constitute several co-occurring neurobiological dimensions that still need further sorting. Heterogeneity has not been adequately captured, and breakthroughs in characterizing mechanistic subtypes, if they exist, are sorely needed.

It seems increasingly clear that ADHD is best conceived, at least in the main, as a disorder of self-control and self-regulation, with the regulation of attention as just one component of this fundamental issue. In this way, the conception is related to a wide range of life outcomes and problems that do not rise to the level of frank ADHD; it also helps explain why nearly all self-control related outcomes can be traced to ADHD as a risk factor, from drug abuse to underemployment.

Although molecular genetic research in ADHD both has increased hugely and to some extent has disappointed observers in the past decade, it is likely that findings in molecular genetics will continue to transform understanding of behavior, development, and ADHD. The movement toward epigenetic analysis is likely to be even more transformative, even if it is slow because of the need to develop appropriate methods for study of human brain function from this perspective.

Neuroimaging is likely to continue to be informative with regard to pathophysiology, but will face the challenge of how the pathophysiology may be translated into clinical utility. The most likely benefit will be in clarifying pathophysiology so that ideas for treatment not yet imagined can be identified.

Key to understanding ADHD may be the notion that it is actually a disorder of performance, rather than skill; of how intelligence is applied in everyday effective adaptive functioning, rather than intelligence itself; of "doing what you know," rather than "knowing what to do"; and of when, rather than how, to perform behavior generally. The concept of time, how it is sensed, and particularly how one uses it in self-regulation are coming to be critical elements in our understanding of ADHD (Barkley, 2012c), as they have already been in our understanding of the unique role of the prefrontal cortex more generally (Fuster, 1997). Likewise, the study of how events are mentally represented and prolonged in working memory, and of how private thought arises out of initially public behavior through the developmental process of internalization, are likely to hold important pieces of information for the understanding of ADHD itself. And as the evolutionary (adaptive) purposes of the prefrontal lobes and the executive functions they mediate come to be better understood (Barkley, 2012c), it is highly likely that these findings will yield a rich vein of insights into the sorts of adaptive deficits caused by ADHD.

ACKNOWLEDGMENTS

During the preparation of this chapter, Joel T. Nigg was supported by National Institutes of Health Grant Nos. MH59105 and MH86654.

NOTES

1. Confirmatory factor analyses of the DSM-IV and DSM-5 item sets do show a slightly better fit for a model with three factors (impulsivity, hyperactivity, inattention) than two, but the fit is also very good with a two-factor solution. Therefore, the expert committees for DSM-IV and DSM-5 opted for the simpler model.

2. DSM-5 has changed the age of onset from 7 years to 12 years, reduced the cutoff point for diagnosing ADHD in adults from six symptoms to five symptoms, and allowed concurrent diagnosis of ADHD and autism spectrum disorder. These changes are expected to have minimal effects on epidemiology or clinical practice, but make the criteria more congruent with empirical findings.

CHAPTER 3

Conduct and Oppositional Defiant Disorders

EVA R. KIMONIS
PAUL J. FRICK
ROBERT J. McMAHON

Oppositional defiant disorder (ODD) and conduct disorder (CD), often collectively termed "conduct problems," are among the most common disorders for which children and adolescents are referred for mental health treatment. For example, 40% of children referred for mental health treatment by a primary care provider were diagnosed with a conduct problem; this percentage was surpassed only by the 50% for attention-deficit/hyperactivity disorder (ADHD) (Rushton, Bruckman, & Kelleher, 2002). This high rate may be attributed to the significant disruption and distress these children's behavior causes to family members, peers, and school personnel. Societal consequences and costs associated with the antisocial and criminal behaviors of youth with conduct problems are substantial, and even more so when these problems develop at younger ages. One estimate suggests that the potential value of saving a single high-risk youth from a criminal career ranges from $3.2 to $5.5 million (Cohen & Piquero, 2009).

ODD and CD are typically first diagnosed in childhood or adolescence, and fall into the broader dimension of mental disorders characterized by disinhibition or externalizing behaviors (American Psychiatric Association [APA], 2013). Factor-analytic research supports the distinction between the angry and defiant behaviors forming the diagnostic criteria for ODD and the antisocial and aggressive behaviors forming the criteria for CD (Frick et al., 1992; Lahey et al., 2008). However, all disorders within the externalizing domain appear to share substantial genetic influences, suggesting at least some common causal factors between them (Lahey, Van Hulle, Singh, Waldman, & Rathouz, 2011; Markon & Krueger, 2005). This externalizing dimension contrasts with a second broad dimension that conceptually organizes overcontrolled or internalizing symptoms of common child and adolescent mental disorders. Internalizing symptoms include social withdrawal, anxiety, and depression (see Hammen, Rudolph, & Abaied, Chapter 5, and Higa-McMillan, Francis, & Chorpita, Chapter 8, this volume). A number of factor-analytic studies support the distinction of these symptoms from those captured by the externalizing domain (Achenbach, 1995; Lahey et al., 2008).

BRIEF HISTORICAL CONTEXT AND CONTROVERSIES

CD first appeared as a psychiatric diagnosis in the second edition of APA's (1968) *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II). The diagnosis involved antisocial, aggressive, and delinquent behavior that was believed to be a reaction to pathological environmental factors, but, like most diagnostic criteria in this early DSM, the criteria for CD were poorly defined. The DSM-II definition also distinguished among

children and adolescents who showed specific types of conduct problems (i.e., runaway reaction, unsocialized aggressive reaction, and group delinquent reaction), highlighting the important issue of subtyping that continues to influence diagnostic classification of CD today.

The current distinction between ODD and CD was first introduced in DSM-III (APA, 1980). Since this time, the predictive validity of CD has been well established (Moffitt et al., 2008). CD is associated with a variety of adjustment problems across the lifespan, including mental health problems (e.g., substance abuse), legal problems (e.g., risk for arrest), educational problems (e.g., school dropout), social problems (e.g., poor marital adjustment), occupational problems (e.g., poor job performance) and physical health problems (e.g., poor respiratory function) (Odgers et al., 2007, 2008). Even among young children (ages 4 and 5), CD predicted significant behavioral and educational difficulties 5 years later (Kim-Cohen et al., 2009).

In contrast, since it was first included in formal classification systems, significant concerns have been raised about the diagnosis of ODD. These concerns largely focus on two issues (Moffitt et al., 2008). The first issue is that the oppositional and argumentative behaviors that form the criteria for ODD are commonly displayed in normally developing children. The second issue is that ODD frequently co-occurs with a host of other adjustment problems. These issues have led some to suggest that the diagnosis overpathologizes normative behavior and, unless accompanied by another disorder, is transient and benign, not warranting consideration as a separate disorder. However, in their review, Frick and Nigg (2012) report on substantial evidence indicating that ODD predicts problems in adjustment (e.g., later antisocial behavior, substance use, and emotional disorders)—even after research controls for the presence of the most common co-occurring childhood disorders (i.e., ADHD and CD)—and that it has predictive power in children as young as 3–5 years of age (e.g., Gadow & Nolan, 2002). This evidence suggests that ODD has important clinical utility and that abandoning its diagnosis is not warranted.

DESCRIPTION OF THE DISORDERS

Core Symptoms

In DSM-5 (APA, 2013), ODD and CD are subsumed under the rubric of the disruptive, impulse-control, and conduct disorders, along with intermittent explosive disorder, pyromania, and kleptomania. Disorders in this category involve problems in the self-control of emotions and behaviors. Whereas many other psychiatric disorders may also involve problems in emotional and/or behavioral regulation, these disruptive disorders are unique in that the problems associated with them are manifested in behaviors that violate the rights of others (e.g., aggression, destruction of property) and/or that bring the individual into significant conflict with societal norms or authority figures (APA, 2013).

The specific diagnostic criteria for ODD include a recurrent pattern of angry, irritable, argumentative, defiant, or vindictive behavior that persists for at least 6 months (see Table 3.1). Factor-analytic studies converge on a three-dimensional conceptualization of the criteria (Burke, 2012; Burke, Hipwell, & Loeber, 2010; Rowe, Costello, Angold, Copeland, & Maughan, 2010). Although item loadings vary somewhat across samples, these studies are consistent in suggesting that the angry–irritable mood dimension (e.g., loses temper, angry/resentful) forms a separate factor from the defiant–headstrong behavior dimension (e.g., argues with adults, defiant/noncompliant). What is less clear from these analyses is the appropriate placement of the symptom given in DSM-IV as "is often spiteful and vindictive" (APA, 2000, p. 102). This symptom has been included on its own to comprise the hurtful dimension, since it does not consistently load with the other two symptom dimensions (Burke, Hipwell, & Loeber, 2010; Rowe et al., 2010) and may be more related to the severe conduct problems of CD (Stingaris & Goodman, 2009). Also, the three dimensions are highly correlated, with *r*'s ranging from .62 to .78 (Stingaris & Goodman, 2009). This suggests that a large number of youth scoring high on one dimension would also show elevated scores on another. This research has influenced DSM-5, which organizes ODD symptoms into these three clusters: angry/irritable mood, argumentative/defiant behavior, and vindictiveness (Table 3.1).

CD is defined as a repetitive and persistent pattern of behavior that violates the rights of others or in which major age-appropriate societal norms or rules are violated (APA, 2013). CD symptoms fall into four dimensions, which have remained unchanged from DSM-IV to DSM-5 (see Table 3.2):

- Aggression to people and animals
- Destruction of property
- Deceitfulness or theft
- Serious violations of rules

TABLE 3.1. DSM-5 Diagnostic Criteria for Oppositional Defiant Disorder

A. A pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness lasting at least 6 months as evidenced by at least four symptoms from any of the following categories, and exhibited during interaction with at least one individual who is not a sibling.

Angry/Irritable Mood

1. Often loses temper.
2. Is often touchy or easily annoyed.
3. Is often angry and resentful.

Argumentative/Defiant Behavior

4. Often argues with authority figures or, for children and adolescents, with adults.
5. Often actively defies or refuses to comply with requests from authority figures or with rules.
6. Often deliberately annoys others.
7. Often blames others for his or her mistakes or misbehavior.

Vindictiveness

8. Has been spiteful or vindictive at least twice within the past 6 months.

Note: The persistence and frequency of these behaviors should be used to distinguish a behavior that is within normal limits from a behavior that is symptomatic. For children younger than 5 years, the behavior should occur on most days for a period of at least 6 months unless otherwise noted (Criterion A8). For individuals 5 years or older, the behavior should occur at least once per week for at least 6 months, unless otherwise noted (Criterion A8). While these frequency criteria provide guidance on a minimal level of frequency to define symptoms, other factors should also be considered, such as whether the frequency and intensity of the behaviors are outside a range that is normative for the individual's developmental level, gender, and culture.

B. The disturbance in behavior is associated with distress in the individual or others in his or her immediate social context (e.g., family, peer group, work colleagues), or it impacts negatively on social, educational, occupational, or other important areas of functioning

C. The behaviors do not occur exclusively during the course of a psychotic, substance use, depressive, or bipolar disorder. Also, the criteria are not met for disruptive mood dysregulation disorder.

Specify current severity:

Mild: Symptoms are confined to only one setting (e.g., at home, at school, at work, with peers).

Moderate: Some symptoms are present in at least two settings.

Severe: Some symptoms are present in three or more settings.

Subtypes

Youth with conduct problems are quite heterogeneous with regard to their behavioral manifestations, causal influences, developmental courses, associated risk factors, and responses to intervention (McMahon & Frick, 2007; McMahon, Wells, & Kotler, 2006). Therefore, understanding this heterogeneity is critical for both causal research and effective intervention. A number of different methods for classifying youth with conduct problems into more homogeneous subgroups have been proposed—starting with the distinction between ODD and CD, but also considering other dimensions (such as the age at which the serious behaviors emerge) or considering the presence of comorbid conditions, the presence of aggression, or the presence of a callous and unemotional interpersonal style.

Childhood- and Adolescent-Onset Subtypes

Within the diagnosis of CD, perhaps the most commonly used method for subtyping is based on the age at which antisocial behavior first emerges. This subtyping method focuses on whether a child's CD symptoms emerge prior to adolescence (i.e., childhood onset) or coincide with the onset of adolescence (i.e., late onset or adolescent onset)—a distinction that is well supported by research (for reviews, see Frick & Viding, 2009; Moffitt, 2006). The childhood-onset group is more

TABLE 3.2. DSM-5 Diagnostic Criteria for Conduct Disorder

A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least three of the following 15 criteria in the past 12 months from any of the categories below, with at least one criterion present in the past 6 months:

Aggression to People and Animals

1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun).
4. Has been physically cruel to people
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

Destruction of Property

8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others' property (other than by fire setting).

Deceitfulness or Theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

Serious Violations of Rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years.
14. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period.
15. Is often truant from school, beginning before age 13 years.

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Specify whether:

312.81 (F91.1) Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.

312.82 (F91.2) Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.

312.89 (F91.9) Unspecified onset: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before or after age 10 years.

Specify if:

With limited prosocial emotions: To qualify for this specifier, an individual must have displayed at least two of the following characteristics persistently over at least 12 months and in multiple relationships and settings. These characteristics reflect the individual's typical pattern of interpersonal and emotional functioning over this period and not just occasional occurrences in some situations. Thus, to assess the criteria for the specifier, multiple information sources are necessary. In addition to the individual's self-report, it is necessary to consider reports by others who have known the individual for extended periods of time (e.g., parents, teachers, co-workers, extended family members, peers).

Lack of remorse or guilt: Does not feel bad or guilty when he or she does something wrong (exclude remorse when expressed only when caught and/or facing punishment). The individual shows a general lack of concern about the negative consequences of his or her actions. For example, the individual is not remorseful after hurting someone or does not care about the consequences of breaking rules.

Callous—lack of empathy: Disregards and is unconcerned about the feelings of others. The individual is described as cold and uncaring. The person appears more concerned about the effects of his or her actions on himself or herself, rather than their effects on others, even when they result in substantial harm to others.

(continued)

TABLE 3.2. *(continued)*

Unconcerned about performance: Does not show concern about poor/problematic performance at school, at work, or in other important activities. The individual does not put forth the effort necessary to perform well, even when expectations are clear, and typically blames others for his or her poor performance.

Shallow or deficient affect: Does not express feelings or show emotions to others, except in ways that seem shallow, insincere, or superficial (e.g., actions contradict the emotion displayed; can turn emotions "on" or "off" quickly) or when emotional expressions are used for gain (e.g., emotions displayed to manipulate or intimidate others).

Specify current severity:

Mild: Few if any conduct problems in excess of those required to make the diagnosis are present, and conduct problems cause relatively minor harm to others (e.g., lying, truancy, staying out after dark without permission, other rule breaking).

Moderate: The number of conduct problems and the effect on others are intermediate between those specified in "mild" and those in "severe" (e.g., stealing without confronting a victim, vandalism).

Severe: Many conduct problems in excess of those required to make the diagnosis are present, or conduct problems cause considerable harm to others (e.g., forced sex, physical cruelty, use of a weapon, stealing while confronting a victim, breaking and entering).

likely to show aggressive behaviors in childhood and adolescence (Moffitt, Caspi, Dickson, Silva, & Stanton, 1996) and to continue antisocial behavior into adulthood, compared with the adolescent-onset group (Odgers et al., 2007). Childhood-onset conduct problems are also more strongly associated with a host of neuropsychological, cognitive, temperamental, familial, and psychosocial risk factors than is the adolescent-onset type (Frick & Viding, 2009; Moffitt, 2006). Youth with adolescent-onset CD show fewer risk factors, although they tend to score higher on measures of rebelliousness and rejection of conventional values than those in the childhood-onset group (Dandreaux & Frick, 2009; Moffitt et al., 1996).

Although it was long thought that adolescent-onset CD reflected an exaggeration of normative adolescent behavior and was limited to the adolescent period, the picture now appears far less optimistic. According to the Dunedin data that initially led Moffitt (1993) to propose the taxonomy, individuals with adolescent-onset CD continue to show significant levels of antisocial activity into their mid-20s and early 30s, as well as various other problems in life adjustment (e.g., impulsivity, substance-related problems, financial difficulties, physical health problems); these findings have led to abandonment of the once-used term "adolescence-limited" (Moffitt, Caspi, Harrington, & Milne, 2002; Odgers et al., 2008). Furthermore, access to opportunities (e.g., gainful employment, higher education) may be limited for these individuals through their encounter of "snares" related to early delinquent involvement, such as substance use disorders, a criminal record, or teen parenthood.

Despite the strong support for this method of subtyping youth with antisocial behaviors, there are also several important limitations to this approach. First, the exact age at which to differentiate childhood- from adolescent-onset CD is not firmly established. In an early test of the differential predictive utility of various age cutoffs, Robins (1966) found that youth who were 11 years of age or younger at the onset of their serious conduct problems were over twice as likely as those over 11 to be diagnosed with antisocial personality disorder as adults. Since that time, age cutoffs for defining the childhood-onset group have ranged from 10 years (APA, 2000, 2013) to 14 years (Patterson & Yoerger, 1997; Tibbetts & Piquero, 1999) for the onset of the first serious conduct problem or first arrest. This difficulty in defining a clear cutoff point for the age of onset has led some researchers to suggest that this distinction should be more dimensional than categorical (Lahey, Waldman, & McBurnett, 1999b). However, a cutoff age of 10 years has been maintained in DSM-5 for distinguishing between the childhood- and adolescent-onset subtypes (APA, 2013).

Accurately pinpointing the age at which a child first showed severe conduct problems is often challenging because of difficulties in the retrospective recall of past behaviors, especially for older adolescents (Moffitt et al., 2008). The typical method for establishing age of onset in research is to collect information from multiple sources (e.g., youth self-report, parent report, official

records) and to use the youngest age reported across those sources (Dandreaux & Frick, 2009). The use of both parent and child reports to determine the earliest age of the first serious conduct problem is supported by research showing that parent report and adolescent self-report showed similar median age of onset for antisocial behaviors, and that both were independently correlated with external criteria (e.g. severity of impairment; Lahey, Miller, Gordon, & Riley, 1999). In addition, Farrington, Barnes, and Lambert (1996) reported that self-report may tap behaviors that may not have come to the attention of authorities or parents. Alternatively, parental report and record reviews may capture behaviors to which youth may be unwilling to admit.

Another issue with this broad subtyping approach is that there appear to be important distinctions that can be made *within* the childhood-onset group. First, not all youth with childhood-onset CD continue to show problems into adulthood; at least some show problems that are limited to childhood (Odgers et al., 2007; Tremblay, 2003). For example, those on such a "childhood-limited" pathway, who constituted 24.3% of the Dunedin sample, were found to experience few physical or mental health problems as adults, with the possible exception of internalizing problems among men in middle adulthood (Odgers et al., 2008). Second, although the childhood-onset group generally tends to show more dispositional risk factors than the adolescent-onset group, the type of dispositional risk factors may vary for subgroups of children and adolescents *within* the childhood-onset group (Frick & Viding, 2009). This latter finding has led to research exploring other methods for distinguishing subgroups within the broader category of childhood-onset CD.

Subtypes Based on Co-Occurring Conditions

Other attempts to separate unique subgroups within the childhood-onset type focus on the presence of co-occurring conditions, such as ADHD (Lynam, 1996). Children with comorbid ADHD and conduct problems show a more severe and aggressive pattern of antisocial behavior than do children with conduct problems alone (Lilienfeld & Waldman, 1990; Waschbusch, 2002). In addition, the combination of ADHD and conduct problems predicts poorer outcomes, including higher rates of adolescent delinquency and adult arrests (Babinski, Hartsough, & Lambert, 1999; Loeber, Brinthaupt, & Green, 1990). This approach to subtyping is also limited, however, as the vast majority of children with childhood-onset CD show comorbid ADHD, especially those referred for treatment (Abikoff & Klein, 1992). As a result, this method of subtyping often fails to designate a group of youth that is very distinct from the larger group defined by an early age of onset.

Subtypes Based on Aggression

Another approach to subtyping children within childhood-onset CD is to distinguish between those with aggressive and those with nonaggressive behavior problems (APA, 1980; Frick et al., 1993). More recent extensions of this approach focus on the two distinct types of aggressive behavior exhibited by children or adolescents with aggressive conduct problems (Poulin & Boivin, 2002). Specifically, "reactive" aggression is characterized by impulsive, defensive responses to a real or perceived provocation or threat. In contrast, "proactive" or "instrumental" aggression is not associated with provocation, but is defined as aggression in pursuit of an instrumental goal (i.e., for gain) and is usually premeditated and planned (Dodge & Pettit, 2003).

Reactive and proactive aggression show different correlates. For example, proactive aggression is more highly correlated with delinquency and alcohol abuse in adolescence, as well as criminality in adulthood (Pulkkinen, 1996; Vitaro, Brendgen, & Tremblay, 2002), whereas reactive aggression is more highly correlated with school adjustment problems and peer rejection (Poulin & Boivin, 2000; Waschbusch, Willoughby, & Pelham, 1998). The two types of aggression are also associated with different social-cognitive and emotional characteristics. Specifically, proactive aggression is associated with a tendency to overestimate the possible positive consequences of aggressive behavior and to underestimate the probability of getting punished for bad behavior (Price & Dodge, 1989; Schwartz et al., 1998), whereas reactive aggression is associated with a tendency to attribute hostile intent to ambiguous provocations by peers and to difficulties with developing nonaggressive solutions to problems in social encounters (Crick & Dodge, 1996; Hubbard, Dodge, Cillessen, Coie, & Schwartz, 2001). Also, heightened physiological reactivity to perceived provocation often accompanies reactive aggression, but not proactive aggression (Hubbard et al., 2002; Muñoz, 2009; Pitts, 1997).

The utility of the proactive–reactive aggression distinction is hotly debated, despite evidence supporting their distinct correlates (Bushman & Anderson, 2001;

Walters, 2005). A primary concern is the high correlation between the two types of aggression. Two meta-analyses suggest that reactive and proactive types of aggression are correlated in the .64 to .68 range in samples of children and adolescents (Card & Little, 2006; Polman, Orobio de Castro, Koops, van Boxtel, & Merk, 2007). In studies that have explored this relationship, a distinct pattern of overlap between the two types of aggression has emerged. There appear to be two groups of aggressive children: The first shows both proactive and reactive aggressive behavior, and the second group is less aggressive overall and shows only the reactive type of aggression (Crapanzano, Frick, & Terranova, 2010; Dodge & Coie, 1987; Frick, Cornell, Barry, Bodin, & Dane, 2003; Muñoz, 2009; Pitts, 1997). Thus it is possible that differences between the two types of aggression are largely due to more severe aggression in the proactive group.

Callous–Unemotional Traits

Another attempt to define meaningful subgroups of children and adolescents within childhood-onset conduct problems is based on a long history of clinical research showing that psychopathic traits designate an important subgroup of antisocial adults (Cleckley, 1941; Hare, 1993; Lykken, 1995). Historically, the study of psychopathic traits has not focused solely on these individuals' antisocial behavior, but instead emphasizes their affective (e.g., lack of empathy, lack of guilt, shallow emotions) and interpersonal (e.g., egocentricity, callous use of others for own gain) style. Importantly, antisocial adults who also manifest the affective and interpersonal facets of psychopathy show a much more severe, violent, and chronic pattern of antisocial behavior than those who do not (Hare & Neumann, 2008). They also show very different affective, cognitive, and neurological characteristics from those of antisocial individuals without these traits (Blair, Mitchell, & Blair, 2005; Newman & Lorenz, 2003; Patrick, 2007).

Over the past several decades, there have been various attempts to use the affective and interpersonal traits of psychopathy to designate a distinct group of children and adolescents with conduct problems (Forth, Hart, & Hare, 1990; Frick, 2009; McCord & McCord, 1964; Quay, 1964). For example, this approach was the basis for the distinction between "socialized" and "undersocialized" forms of CD that was made in DSM-III (APA, 1980). The following quotation from DSM-III describes the characteristics of the undersocialized type of CD, illustrating its link to the adult construct of psychopathy:

> The Undersocialized types [of CD] are characterized by a failure to establish a normal degree of affection, empathy, or bond with others. Peer relationships are generally lacking, although the youngster may have superficial relationships with other youngsters. Characteristically, the child does not extend himself or herself for others unless there is an obvious immediate advantage. Egocentrism is shown by readiness to manipulate others for favors without any effort to reciprocate. There is generally a lack of concern for the feelings, wishes, and well-being of others, as shown by callous behavior. Appropriate feelings of remorse are generally absent. Such a child may readily inform on his or her companions and try to place blame on them. (APA, 1980, p. 45)

Research on the undersocialized subtype of CD supported its validity, in that adolescents who were classified as such tended to have poorer adjustment in juvenile institutions and were more likely to continue to show antisocial behavior into adulthood compared to other adolescents with CD (Frick & Loney, 1999; Quay, 1987). The undersocialized group was also more likely to show several neurophysiological correlates to their antisocial behavior, such as low serotonin levels and autonomic irregularities (Lahey, Hart, Pliszka, Applegate, & McBurnett, 1993; Quay, 1993; Raine, 1993).

Despite the promising research findings for this subtyping approach, in practice there was considerable confusion over the core features that should define the undersocialized subgroup and differentiate it from other groups of antisocial youth. This confusion was due to two issues. First, in an attempt to avoid using the pejorative term "psychopathy," the term "undersocialized" was used. Unfortunately, this term did not clearly describe the affective or interpersonal features of psychopathy and led to other connotations (e.g., that such a child was not well socialized by parents or was unable to form relationships with peers). Second, the operational definition for the undersocialized subgroup that was provided in the DSM-III listed several indicators, of which no more than one could be present. This list included only one symptom specific to the affective and interpersonal dimensions of psychopathy (i.e., "apparently feels guilt or remorse when such a reaction is appropriate (not just when caught or in difficulty)"; APA, 1980, p. 48). The other four symptoms focused on indicators of social attachment (e.g., " has one or

more peer group friendships that have lasted over six months," "avoids blaming or informing on companions") that have not proven to be reliable indicators of the affective and interpersonal features of psychopathy (Frick, 2009).

This method for classifying subgroups of children with CD was not continued in later editions of the DSM, due to these definitional problems. However, a significant body of contemporary research has emerged refining how the key features associated with psychopathy may be expressed in children and adolescents, and demonstrating the clinical and etiological importance of using these features to designate a distinct subgroup of antisocial youth. Specifically, there appears to be a subgroup of antisocial children and adolescents who show a "callous" (e.g., lack of empathy, absence of guilt, uncaring attitudes) and "unemotional" (e.g., shallow or deficient emotional responses) interpersonal style (Kahn, Frick, Youngstrom, Findling, & Youngstrom, 2012). Youth with childhood-onset CD show higher levels of these callous–unemotional (CU) traits than youth in the adolescent-onset group do (Dandreaux & Frick, 2009; Silverthorn, Frick, & Reynolds, 2001). However, CU traits designate an important subgroup *within* the childhood-onset group (see Figure 3.1). For example, CU traits predict a more severe, stable, and aggressive pattern of behavior within youth who show severe early conduct problems (Kahn et al., 2012; McMahon, Witkiewitz, Kotler, & Conduct Problems Prevention Research Group, 2010; Rowe et al., 2009). Children and adolescents with CU traits also show a more severe and pervasive pattern of aggressive behavior that is more proactive in nature (Flight & Forth, 2007; Frick et al., 2003; Kruh, Frick, & Clements, 2005). Frick, Ray, Thornton, and Kahn (2014) have provided a comprehensive review of research documenting several other emotional, cognitive, personality, and social differences between antisocial youth with and without CU traits. This research is discussed in more detail later in this chapter.

The subtyping of youth with CD on the basis of the presence–absence of CU traits may help to integrate and advance many of the previous subtyping methods. First, although CU traits are more likely to be present in the childhood-onset type, there is also significant support for their predictive utility, even after researchers have controlled for the age of onset of serious antisocial behavior (Loeber et al., 2005; McMahon et al., 2010; Stickle, Kirkpatrick, & Brush, 2009; Vitacco, Caldwell, Van Rybroek, & Gabel, 2007). For example,

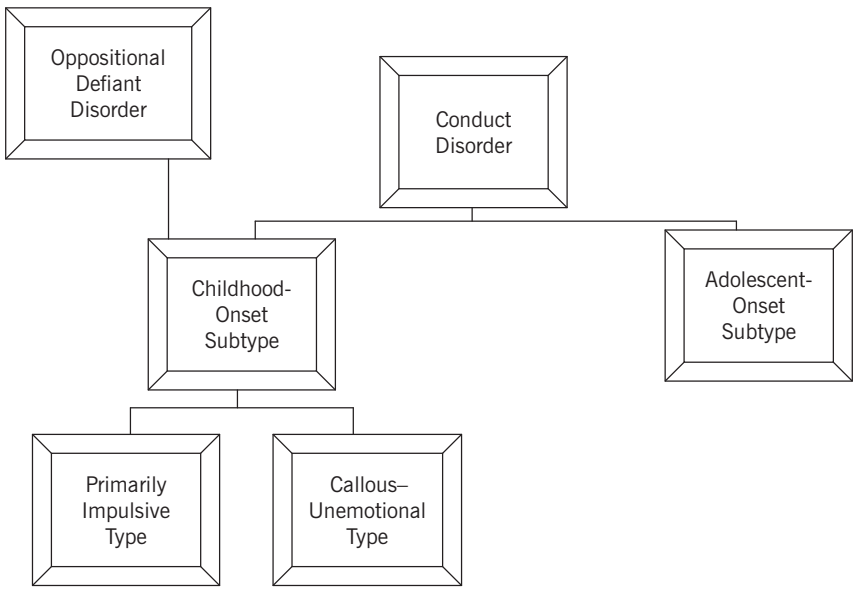

FIGURE 3.1. Developmental pathways to conduct problems.

in a large high-risk community sample ($N = 754$), McMahon and colleagues (2010) reported that CU traits assessed in seventh grade significantly predicted adult antisocial outcomes (e.g., arrests, antisocial personality symptoms), even after controls for diagnoses of ADHD, ODD, CD, and a childhood onset to CD. Second, CU traits seem to be important for designating a subgroup of youth with both CD and ADHD. For example, Barry and colleagues (2000) found that clinic-referred children with ADHD, conduct problems, and CU traits differed from those with ADHD and conduct problems without CU traits by showing a distinct temperamental style characterized by low fearfulness and high reward dominance. Finally, as noted above, children and adolescents with CU traits are more likely to show the combination of reactive and proactive aggression that has also been used to designate an important subgroup of youth with conduct problems. Unfortunately, it is not clear whether the poor outcomes for children with this severe pattern of aggressive behavior are better predicted by the aggressive behavior itself or by the presence of CU traits. However, some of the social-cognitive deficits (e.g., a tendency to emphasize the rewarding aspects of aggressive behavior and ignore the punishments) and some of the emotional characteristics (e.g., lack of emotional responsiveness to provocation) that are associated with proactive aggression may be more specifically associated with CU traits (Muñoz, Frick, Kimonis, & Aucoin, 2008; Pardini, Lochman, & Frick, 2003).

COMMON COMORBIDITIES

In addition to the comorbidity with ADHD mentioned above, children with ODD or CD often have other types of emotional and behavioral problems. ODD in particular is frequently comorbid with a host of other disorders, including emotional disorders (Biederman, Petty, Dolan, et al., 2008; Biederman, Petty, Monuteaux, et al., 2008; Burke, Waldman, & Lahey, 2010; Garland & Garland, 2001; Harpold et al., 2007; Nock, Kazdin, Hiripi, & Kessler, 2007). For example, 10–20% of children with ODD develop internalizing disorders as preschoolers, with somewhat higher rates for older youth (among community samples, 15–46% present with comorbid major depression and 7–14% present with a comorbid anxiety disorder), particularly those with persistent ODD (Boylan, Vaillancourt, Boyle, & Szatmari, 2007). Importantly, the different symptom dimensions that form the criteria for ODD may differentially account for these common comorbid conditions (Frick & Nigg, 2012). To illustrate, a cross-sectional study of 18,415 participants in a national mental health survey in the United Kingdom (ages 5–16) reported that all three dimensions of ODD were related to CD (Stingaris & Goodman, 2009). However, the angry–irritable dimension was also related to emotional disorders; the defiant–headstrong dimension was also related to ADHD; and the spiteful–vindictive symptom was also related to indicators of CU traits (see also Drabick & Gadow, 2012; Ezpeleta, de la Osa, Granero, Penelo, & Domenech, 2012). Similar divergent predictions from the different ODD dimensions have been found longitudinally, with most studies reporting that all three dimensions predict risk for later CD, but that only the angry–irritable dimension also predicts risk for later emotional disorders (Burke, Hipwell, & Loeber, 2010; Rowe et al., 2010; Stingaris & Goodman, 2009).

As noted previously, CD (especially the childhood-onset type) shows considerable comorbidity with ADHD, with up to 41% of community children and adolescents with ODD/CD presenting with comorbid ADHD (Angold, Costello, & Erkanli. 1999). Children with comorbid CD/ODD and ADHD in childhood are at heightened risk for tobacco, alcohol, and illicit drug use in adolescence compared with controls, particularly when CD symptoms are persistent (Molina & Pelham, 2003; Wilens et al., 2011). Moreover, results from a national survey conducted in the Netherlands found that conduct problems fully explained the relationship between ADHD and alcohol use disorder (Tuithof, ten Have, van den Brink, Vollebergh, & de Graaf, 2012). CD also often co-occurs with anxiety and mood disorders (Boylan et al., 2007). It is estimated that one-third of children in the community and three-quarters of those who are clinic-referred with CD meet diagnostic criteria for a comorbid depressive and/or anxiety disorder (Russo & Beidel, 1994; Zoccolillo, 1993). The development of internalizing problems, particularly depression, among youth with conduct problems has been attributed to their frequent interpersonal conflicts (e.g., with parents, peers, teachers, and police) and to other stressors (e.g., family dysfunction, school failure) that often result from the youth's problematic behavior (Capaldi, 1991; Frick, Lilienfeld, Ellis, Loney, & Silverthorn, 1999). Much of the overlap between CD and internalizing problems may be attributed to co-occurring ODD (Loeber, Burke, & Pardini, 2009). Specifically,

the presence of the angry and irritable ODD symptoms may help to designate a group of children with CD who have problems with emotional regulation (Frick & Morris, 2004; Lahey & Waldman, 2003), which may place them at particular risk for developing emotional disorders (Burke, Hipwell, & Loeber, 2010; Drabick & Gadow, 2012; Ezpeleta et al., 2013; Rowe et al., 2010).

DEFINITIONAL AND DIAGNOSTIC ISSUES

As discussed in the "Core Symptoms" section above, there is support for recognizing three important symptom domains within ODD, as reflected in the DSM-5 criteria (see Table 3.1): angry/irritable mood, argumentative/defiant behavior, and vindictiveness. Another important indicator of the severity of ODD appears to be how pervasive the behaviors are across situations (i.e., at home, at school, with peers). Youngstrom (2011) conducted secondary data analyses on 292 clinic-referred youth diagnosed with ODD. Of those meeting criteria for ODD, 11% showed impairment only at home, 27% in two settings, and 62% in all three settings. Most importantly, the minority who reportedly had impairments only at home still showed significant problems in adjustment, albeit not as significant as the problems shown by those with impairments in two or more settings. Furthermore, those impaired in two settings showed fewer problems in adjustment than those impaired in all three settings. Similarly, ODD reported by parents alone has been associated with significant problems in adjustment, albeit not as severe as when it was reported by multiple informants (Drabick, Gadow, & Loney, 2007). Finally, Wakschlag and colleagues (2007) found that it was not unusual for preschool children with ODD to show problems in only one of three interactional contexts (i.e., two with a parent and one with an experimenter); however, those who showed problems in more than one setting had more severe behavioral disturbance.

With respect to CD, the importance of recognizing the utility of CU traits for distinguishing a distinct subgroup of youth is reflected by the incorporation of these traits into the diagnosis of CD in DSM-5. DSM-5 includes a specifier to CD for children "with limited prosocial emotions" (see Table 3.2). Specifically, for children who meet criteria for CD, the specifier would be given if the child persistently shows two or more of the following characteristics over at least 12 months and in multiple relationships and settings:

- Lack of remorse or guilt
- Callous—lack of empathy
- Lack of concern about performance (at school, at work, or in other important activities)
- Shallow or deficient affect

One of the driving concerns that led to referring to this constellation of traits as "with limited prosocial emotions" was the pejorative connotation associated with the term "callous–unemotional" (see Frick & Nigg, 2012). Although there is no research directly testing the effects of the label "CU traits," there is an empirical literature studying the negative effects of the use of the term "psychopathy" when applied to children and adolescents (for a review, see Murrie, Boccaccini, McCoy, & Cornell, 2007). To summarize, the findings indicate that the term "psychopathy" does affect the decisions made by professionals (e.g., clinicians' estimation of treatability), but it does not have any more negative effects than using the term "conduct disorder" itself. Thus it appears that any term used to describe individuals with antisocial behavior or traits will acquire negative connotations. Also, as noted above, previous attempts to capture CU traits in DSM used the term "undersocialized" to minimize the potentially stigmatizing effects of the label. It is not clear, however, that this term has any fewer negative connotations than the others; moreover, its lack of clarity led to considerable variability in how the construct was conceptualized and assessed by researchers and clinicians. Finally, there is a danger in using terms that appear to connote a less severe disturbance (e.g., "uncaring") for the specifier, in an effort to decrease the potential for stigmatization. Such definitions could actually be more harmful by leading clinicians to assign formal diagnoses to children and adolescents who are less impaired. These considerations led to the choice of "with limited prosocial emotions" for the specifier for CD in DSM-5; this label reflects the focus of the criteria on the absence of guilt, a callous lack of empathy, and the lack of interest in living up to others' expectations, which are characteristics whose primary function is to promote prosocial behavior (Eisenberg & Miller, 1987).

DEVELOPMENTAL COURSE AND PROGNOSIS

The development of ODD and CD can vary greatly across subgroups of youth with these disorders. Many investigators consider ODD to be a developmental pre-

cursor to CD, especially for those with a childhood onset (Burke, Waldman, & Lahey, 2010; Moffitt et al., 2008). In many children with childhood-onset CD, ODD emerges first, followed by the onset of mild CD symptoms as early as preschool or early elementary school. Over the course of childhood and into adolescence, these behaviors gradually escalate into patterns of increasingly frequent and severe conduct problems (Kim-Cohen et al., 2009; Loeber, Lahey, & Thomas, 1991; Shaw, Gilliom, Ingoldsby, & Nagin, 2003). Beauchaine, Hinshaw, and Pang (2010) further explain that the typical developmental course for delinquent behavior in boys begins with severe hyperactive–impulsive behaviors in early childhood, followed by ODD at preschool age, childhood-onset CD at elementary school age, substance-related disorders in adolescence, and antisocial personality disorder in adulthood. However, a large proportion of children with ODD do not go on to develop CD (Maughan, Rowe, Messer, Goodman, & Meltzer, 2004; Rowe, Maughan, Pickles, Costello, & Angold, 2002). To illustrate, in the Developmental Trends longitudinal study, approximately three-quarters of children diagnosed with ODD did not exhibit CD within 3 years (Hinshaw, Lahey, & Hart, 1993).

Extensive research supports divergent life course trajectories for childhood- versus adolescent-onset CD. Specifically, beyond adolescence the antisocial and criminal behavior of individuals with childhood-onset CD tends to be more severe than that of persons with adolescent-onset CD (Odgers et al., 2007). For example, in a prospective study of the adult outcomes of a birth cohort in New Zealand (i.e., Dunedin Study), Odgers and colleagues (2008) compared two groups of adults (age 32) who had severe conduct problems as youth. The childhood-onset group (those who began showing serious problems prior to puberty) made up only 10.5% of the male and 7.5% of the female birth cohort. Compared with the adolescent-onset group, which made up 19.6% of the male and 17.4% of the female birth cohort, childhood-onset men were over four times more likely to be convicted of a violent offense between the ages of 26 and 32, and women were almost four times more likely to engage in informant-reported violence (official convictions not available) and six times more likely to engage in intimate-partner violence. A prior follow-up of the men in this cohort demonstrated that at age 26 the childhood-onset group accounted for 43% of violent convictions, 40% of drug convictions, and 62% of convictions for violence against women in the sample. In contrast, the adolescent-onset group was 50–60% less likely to be convicted of an adult offense, and their offenses tended to be less serious (e.g., minor theft, public drunkenness) and less violent (e.g., accounting for 50% of the convictions for property offenses) (Moffitt et al., 2002). As noted previously, youth with conduct problems emerging in adolescence continue to show antisocial behavior and impairments in adjustment (e.g., financial problems) that persist into adulthood, but that are less related to enduring psychosocial vulnerabilities (e.g., neuropsychological impairments, deficits in social skills) and are usually direct consequences of their antisocial behaviors (e.g., poor educational attainment, criminal records) (Moffitt & Caspi, 2001; Moffitt et al., 2002).

The subgroup of children with CU features seems to exhibit a particularly stable pattern of antisocial behavior. For example, Byrd, Loeber, and Pardini (2012) reported that parent and teacher-rated CU traits at age 7 predicted criminal behavior at age 25 among a sample of boys (N = 503), even after the researchers controlled for childhood ODD, CD, and ADHD. Similarly, two studies report that CU traits in childhood are significantly associated with measures of psychopathy in adulthood, after controls for childhood conduct problems and other risk factors for antisocial behavior (Burke, Loeber, & Lahey, 2007; Lynam, Caspi, Moffitt, Loeber, & Stouthamer-Loeber, 2007).

EPIDEMIOLOGY

Prevalence

It is estimated that between 2 and 16% of youth in community settings present with significant conduct problems (i.e., ODD and/or CD), with higher estimates within clinic settings (Boylan et al., 2007; Loeber, Burke, Lahey, Winters, & Zera, 2000). A recent meta-analysis of the worldwide prevalence of both ODD and CD among children and adolescents ages 6–18 years reported overall pooled prevalence estimates of 3.3% for ODD and 3.2% for CD, based on epidemiological surveys (Canino, Polanczyk, Bauermeister, Rohde, & Frick, 2010). These estimates did not vary significantly across countries, but did vary depending on the restrictiveness of the criteria used to make the diagnosis. As would be expected, definitions that did not require substantial impairment to be associated with the conduct problems resulted in higher prevalence estimates.

Sex Differences

Most studies find that boys are more likely to show conduct problems than girls. However, gender differences in the prevalence of conduct problems vary somewhat across development. At preschool age, gender differences are small and sometimes nonexistent. Prevalence estimates indicate that ODD is diagnosed at an equivalent rate between boys and girls (Keenan & Shaw, 1997; Maughan et al., 2004). This changes at school age, when ODD and CD are both two to three times more likely to be diagnosed in boys than in girls (Lavigne, Lebailly, Hopkins, Gouze, & Binns, 2009; Moffitt, Caspi, Rutter, & Silva, 2001). This gap closes to about 2:1 by adolescence, when both boys and girls show a dramatic increase in the rates of ODD and CD (Loeber et al., 2000).

It is unclear whether developmental changes in prevalence rates are real differences or are artifacts of diagnostic criteria that are insensitive to sex differences in the expression of conduct problems. An important topic of debate is whether or not there should be gender-specific criteria for CD. Two specific potential sources of bias in the existing CD criteria have been considered (Frick & Nigg, 2012). First, some question whether the threshold for the diagnosis of CD (i.e., three symptoms) is too high for girls. This has led some to propose that gender-specific thresholds should be used (Zoccolillo, Tremblay, & Vitaro, 1996). Girls with one or two CD symptoms show impairments in their functioning both concurrently (Keenan, Wroblewski, Hipwell, Loeber, & Stouthamer-Loeber, 2010) and predictively (Messer, Goodman, Rowe, Meltzer, & Maughan, 2006). Although girls with subclinical levels of CD are at risk for current and future impairment, the three-symptom threshold still designates a substantially more impaired group than those with either one or two symptoms (Keenan et al., 2010).

A second consideration is whether the symptoms that form the CD criteria should be broadened to include the types of conduct problems that are more likely to be exhibited by girls. Namely, when girls behave aggressively, they exhibit indirect or relational forms of aggression (e.g., spreading rumors, attempts to harm one person's relationships with others) more often than physical forms of aggression (e.g., attempts to physically harm others) (Crapanzano et al., 2010; Underwood, 2003). In support of this proposition, a significant number of girls who show relational, but not physical, aggression present with impaired social functioning (i.e., bullying) and display a number of other risk factors often associated with CD (e.g., anger dysregulation, impulsivity; Crapanzano et al., 2010). In one of the few studies directly testing the incremental utility of relational aggression to the criteria for ODD and CD in girls, girls scoring high on relational aggression also exhibited higher rates of ODD and CD symptoms (Keenan, Coyne, & Lahey, 2008). However, those girls scoring high on relational aggression but without either diagnosis were not significantly more impaired than those who were not high on relational aggression. Thus the research basis does not appear strong enough at present to warrant developing gender-specific criteria for CD (Frick & Nigg, 2012; Moffitt et al., 2008).

One additional issue related to the cross-gender diagnosis of CD relates to the relevance of the current subtypes. A robust finding is that childhood-onset CD occurs less frequently in girls than in boys (Moffitt & Caspi, 2001; White & Piquero, 2004). For example, in an entire birth cohort of New Zealand children, only six girls with childhood-onset CD were identified, in contrast to larger groups of adolescent-onset girls (n = 78), childhood-onset boys (n = 47), and adolescent-onset boys (n = 122; Moffitt & Caspi, 2001). Similarly, in an adjudicated sample of adolescent boys and girls, an almost equal number of boys had a childhood onset (46%) or adolescent onset (54%) to their severe antisocial behavior, whereas 94% of girls had an adolescent onset to their antisocial behavior (Silverthorn et al., 2001). Despite the predominance of adolescent-onset CD in girls, there is evidence that these girls present with a large number of the dispositional and contextual risk factors associated with childhood-onset CD in boys (Frick & Dickens, 2006). For example, girls with CD often show poor outcomes in adulthood, such as high rates of criminality, violence, antisocial personality disorder, and other psychiatric disorders (Zoccolillo, 1993).

To reconcile these findings, Silverthorn and Frick (1999) have proposed that a small number of girls may show a childhood onset to their conduct problem behavior and may present similarly to boys with childhood-onset CD. However, despite having early risk factors similar to those of childhood-onset boys, girls with CD are more likely to show an adolescent onset to their conduct problems, which Silverthorn and Frick have described as a "delayed-onset pathway" to CD. They propose that among girls with predisposing vulnerabilities (e.g., CU traits, problems in emotional regulation), severe conduct problem behavior is often

delayed until adolescence, coinciding with biological (e.g., hormonal changes associated with puberty) and psychosocial (e.g., less parental monitoring and supervision, greater contact with deviant peers) changes that encourage these behaviors. In an initial test of this theory, adjudicated adolescent girls who largely showed an adolescent onset to their conduct problems also showed high levels of CU traits, problems with impulse control, and several other social and temperamental vulnerabilities that were more similar to those of childhood-onset boys than to those of adolescent-onset boys (Silverthorn et al., 2001). Despite this initial positive finding, additional tests of this model have been mixed (Moffitt & Caspi, 2001; Odgers et al., 2008; White & Piquero, 2004). Thus the possibility of a delayed-onset trajectory in girls does not appear to currently have the support necessary for integration into diagnostic classification systems for CD.

Cultural Variations

The evidence for cultural variations in ODD and CD is mixed. A review of 25 epidemiological studies conducted in 16 different countries found highly consistent prevalence rates for ODD and CD across countries that differed in their cultural composition (Canino et al., 2010). However, within the United States, higher rates of conduct problems in African American youth have been found in some samples (Fabrega, Ulrich, & Mezzich, 1993) but not others (McCoy, Frick, Loney, & Ellis, 2000). Also, lower rates of CD have been reported for Americans of Asian descent than for European Americans and African Americans (Compton, Conway, Stinson, Colliver, & Grant, 2005). More importantly, it is unclear whether any association between minority status and conduct problems is independent of the fact that some ethnic minorities are more likely to experience economic hardships and live in urban neighborhoods with higher concentrations of crime than nonminority individuals (Lahey, Waldman, & McBurnett, 1999). With the growing immigrant populations in the United States, risk for CD appears to vary according to migration status and level of exposure to American culture. For example, a study found that risk for CD was highest among Mexican American children of U.S.-born parents (odds ratio = 7.64), compared with Mexican-born immigrants raised in the United States (odds ratio = 4.12) and the general population of Mexico (odds ratio = 0.54; Breslau, Saito, Tancredi, Nock, & Gilman, 2012).

RISK AND PROTECTIVE FACTORS

A significant amount of research focuses on understanding the causes of childhood and adolescent conduct problems. This is not surprising, given the associated levels of current and future impairment, as well as the significant costs to society incurred by the criminal and violent behavior that often accompanies conduct problems (for reviews, see Dodge & Pettit, 2003; Frick & Viding, 2009; Moffitt, 2006). This research has resulted in a long list of factors that have been identified as placing a child at risk for acting in an antisocial or aggressive manner (see Table 3.3). They include such dispositional risk factors as genetic predispositions; neurochemical (e.g., low serotonin) and autonomic (e.g. low resting heart rate) irregularities; neurocognitive deficits (e.g., deficits in executive functioning); deficits in the processing of social information (e.g., cognitive biases); temperamental vulnerabilities (e.g., poor emotional regulation); and personality predispositions (e.g., impulsivity). In addition, there are multiple contextual risk factors, including prenatal factors (e.g., exposure to toxins); characteristics of the early environment (e.g., poor-quality child care); family variables (e.g., ineffective discipline, poor attachment); peer variables (e.g., association with deviant peers); and neighborhood characteristics (e.g., high levels of violence exposure). Importantly, ODD and CD typically show the same dispositional and environmental risk factors (Boden, Fergusson, & Horwood, 2010; Rowe et al., 2002).

Although research has been very successful in documenting risk factors for ODD and CD, their number and diversity have led to great debate over the best way to integrate them into a coherent, yet comprehensive, causal model for the development of severe conduct problems. This debate has arisen both because the sheer number of factors is so large and because they involve so many different types of causal processes. There are a few points of agreement, however. First, to adequately explain the development of aggressive and antisocial behaviors associated with conduct problems, causal models must consider the potential role of multiple risk factors. Second, risk factors are also typically not independent of each other and are likely to operate in a transactional fashion (e.g., with one risk factor having an influence on another risk factor) or a multiplicative fashion (as in the case of gene–environment interactions) (Dodge & Pettit, 2003). For example, Jaffee and colleagues (2005) found that childhood-onset conduct problems were more common among chil-

TABLE 3.3. Summary of Risk Factors by Conduct Problem Subtype

Risk factor	ODD	Childhood-onset CD	Adolescent-onset CD	CU traits
Biological				
• Genetic	✓	✓	> ✓	< ✓

Note. Checkmarks are used to indicate risk factors that have been identified as being associated with the specific conduct problem subtype.

dren with a genetic vulnerability to problem behavior who were also exposed to maltreatment. Third, causal models must consider the possibility that subgroups of youth with conduct problems may have distinct causal mechanisms underlying their antisocial and aggressive behaviors. Finally, causal models need to integrate research on the development of conduct problems with research on normally developing youth. For example, research suggests that the ability to adequately regulate emotions and behaviors and the ability to feel empathy and guilt towards others play a role in the development of CD (Frick & Viding, 2009). As a result, understanding the processes involved in the normal development of these abilities is critical for understanding how they may go awry in some children and place them at risk for acting in an aggressive or antisocial manner.

In this section, we provide a causal model for ODD and CD by attempting to integrate previously reviewed research on CD subtypes with the research on the diverse array of risk factors associated with conduct problems. Furthermore, we take a developmental psychopathology approach by linking these risk factors to the specific developmental mechanisms that may lead to the problem behavior.

Dispositional Risk Factors

Genetic Influence

Research employing behavior genetic designs suggests that conduct problems are under at least moderate genetic influence (h^2 = .53–.54; Bornovalova, Hicks, Iacono, & McGue, 2010; Gelhorn et al., 2005). This influence is stronger for aggressive childhood conduct problems (h^2 = .60) than for nonaggressive conduct problems (h^2 = .49; Eley, Lichtenstein, & Stevenson, 1999), and for the childhood-onset subtype than for the adolescent-onset subtype of CD (Moffitt, 2003, 2006). Such findings support the view that the development of conduct problems in the adolescent-onset group is less related to dispositional factors and more related to environmental influences. For those youth with conduct problems and comorbid disorders (e.g., ADHD), research suggests that common genetic factors often explain much of the comorbidity (Bornovalova et al., 2010).

Importantly, the genetic influence on childhood-onset CD seems to be substantially accounted for by youth with significant levels of CU traits (Larsson, Andershed, & Lichtenstein, 2006; Taylor, Loney, Bobadilla, Iacono, & McGue, 2003). The most direct support for this contention comes from a large twin study of 7-year-old children, which reported that the heritability of conduct problems for children high on CU traits was over twice as great (.81) as for children low on CU traits (.30; Viding, Blair, Moffitt, & Plomin, 2005). Differences in heritability could not be attributed to the severity of conduct problems or to levels of impulsivity–hyperactivity (Viding et al., 2005; Viding, Jones, Frick, Moffitt, & Plomin, 2008). In attempting to explore the genetic contributions to CU traits, another twin study reported that left posterior cingulate and right dorsal anterior cingulate gray matter concentrations showed significant heritability (.46 and .37, respectively), and that common genetic factors explained the phenotypic relationship between these regions and CU traits in a sample of boys (Rijsdijk et al., 2010). These data suggest that the genetic contribution to CU traits may be manifested, at least in part, through an impact on anterior and posterior cingulate cortex development.

A particularly promising area of research is investigating potential genetic polymorphisms associated with CU traits. T. Fowler and colleagues (2009) reported that among adolescents (ages 12–19) with childhood ADHD, those either possessing a low-activity monoamine oxidase A receptor (MAOA) allele, homozygous for the low-activity serotonin transporter (5-HTT) allele, or possessing the high activity catechol-*O*-methyltransferase (COMT) Val/Val genotype demonstrated significantly higher levels of CU traits. Also, in a study of 162 children and adolescents (ages 6-16), CU traits were associated with two polymorphisms on the oxytocin receptor (OXTR) gene (Beitchman et al., 2012). Specifically, CU traits were associated with the haplotypes consisting of the OXTR_rs237885 A allele and OXTR_rs2268493es A allele. Since few molecular genetic studies have been undertaken, conclusions about potential genetic polymorphisms that may be related to the development of CU traits should be drawn cautiously. However, these latter findings are particularly promising, given oxytocin's role in affiliation and recognition of others' emotions, both of which are impaired in individuals with CU traits (Campbell, 2010).

Emotional/Temperamental Factors

Various emotional risk factors have been associated with the development of ODD and CD, and problems in emotional regulation play an important role in many theories of their development (Frick & Morris, 2004). There is a robust relationship between ODD and a child

temperament characterized by low effortful control (i.e., poor age-appropriate self-regulation), with more modest associations with child sensory dysregulation and negative affect (Lavigne et al., 2012). Barkley (2010, 2013) has argued that this emotional dysregulation dimension of ODD is largely a consequence of the substantial overlap of ADHD with ODD. He asserts that ADHD, as a disorder of self-regulation, has an inherent deficit in emotional self-control that places children with ADHD at higher risk for comorbid ODD. This deficit in emotional regulation also results in low frustration tolerance, impatience, and quickness to anger. In addition, Barkley argues that children with "pure" ODD are likely to manifest the social conflict aspects of ODD (e.g., arguing) that may be more related to learning within coercive family processes, but are less likely to show its emotional dimension (e.g., anger, irritability, impatience) than are children with both ODD and ADHD.

With respect to CD, emotion regulation problems appear to be more strongly associated with the childhood-onset than the adolescent-onset type (Moffitt et al., 1996). However, within the childhood-onset group, those with and without a CU presentation seem to show different emotional characteristics. Specifically, those without a CU presentation seem to be highly reactive to negative emotional stimuli (Kimonis, Frick, Fazekas, & Loney, 2006; Loney, Frick, Clements, Ellis, & Kerlin, 2003; Muñoz et al., 2008) and to the distress of others (Pardini et al., 2003); they often show high rates of anxiety (Andershed, Gustafson, Kerr, & Stattin, 2002; Frick et al., 1999; Pardini, Lochman, & Powell, 2007); and they appear to be highly distressed by the effects of their behavior on others (Loney et al., 2003; Pardini et al., 2003). These findings suggest that children with conduct problems but without significant levels of CU traits may have difficulties with emotional regulation related to high levels of emotional reactivity.

In contrast, those with non-normative levels of CU traits show deficits in the processing of negative emotional stimuli—and, even more specifically, deficits in their reactivity to signals of fear and distress in others. This is evidenced by their reduced autonomic responses to others' distress (Blair, 1999), reduced recognition of fearful and sad facial expressions (Blair, Colledge, Murray, & Mitchell, 2001; Stevens, Charman, & Blair, 2001), reduced responsiveness to fearful vocal tones (Blair, Budhani, Colledge, & Scott, 2005), reduced focus on the eye region of the face when they are processing fearful expressions (Dadds, El Masry, Wimalaweera, & Guastella, 2008), and reduced attentional orienting to others' distress cues (Kimonis et al., 2006, 2008). Of note, a study by Willoughby, Waschbusch, Propper, and Moore (2011) suggests that these differences in emotional processing between groups of children with conduct problems may be evident very early in life. Specifically, 5-year-old children (n = 178) with high levels of parent-reported CU traits and symptoms of ODD were rated as less soothable and showed less negative reactivity to the "still-face" paradigm (i.e., a parental face showing no emotion or interaction with an infant) at 6 months of age, compared to those with symptoms of ODD but without a CU presentation.

Children with CU traits also tend to show lower levels of fear and anxiety (or neuroticism), especially when research has controlled for co-occurring impulsivity or conduct problems (Frick et al., 2014). For example, Pardini, Stepp, Hipwell, Stouthamer-Loeber, and Loeber (2012) reported on a longitudinal study of 1,862 girls who were ages 5–8 at the initial assessment. Girls with CD who showed significant levels of CU traits exhibited fewer anxiety problems 6 years later than girls with CD but without a CU presentation did. In another study that used a population-based sample (N = 7,000), fearless temperament at age 2 predicted both CU traits and conduct problems at age 13 (Barker, Oliver, Viding, Salekin, & Maughan, 2011). However, in follow-back analyses, youth with high levels of both conduct problems and CU traits at age 13 showed lower fearful responses to punishment cues at age 2, compared to those high on conduct problems but without a CU presentation. These emotional characteristics of children and adolescents with elevated CU traits closely resemble a temperament that has been described as "behaviorally uninhibited" or "fearless." Specifically, uninhibited children tend to seek out novel and dangerous activities, and show less physiological arousal to threats of punishments (Kagan, Reznik, & Snidman, 1988; Rothbart, 1981). Importantly, there is also evidence that children with this uninhibited or fearless temperament are at risk for problems in conscience development (Kochanska, Gross, Lin, & Nichols, 2002; Rothbart, Ahadi & Hershey, 1994), supporting the hypothesis that deficits in the normative development of conscience may be a primary developmental mechanism leading to conduct problems in children with CU traits (Frick & Viding, 2009).

Cognitive Deficits

Consistent with the findings for the other dispositional risk factors, youth with childhood-onset CD tend to

show cognitive deficits in executive functioning and low verbal intelligence (Fergusson, Lynsky, & Horwood, 1996; Kratzer & Hodgins, 1999; Piquero, 2001; Raine, Yaralian, Reynolds, Venables, & Mednick, 2002). Also consistent with findings for the other dispositional risk factors, the specific types of cognitive deficits appear to differ depending on whether or not a youth shows CU traits. Children without CU traits show more severe verbal intelligence deficits (Loney, Frick, Ellis, & McCoy, 1998) and are more likely to attribute hostile intent to the actions of peers (i.e., hostile attribution bias) than those with CU traits (Frick et al., 2003).

In contrast, children and adolescents with conduct problems and CU traits tend to expect more instrumental gain (e.g., obtaining goods or social goals) from their aggressive actions with peers (Pardini et al., 2003). They are also more impaired in their moral reasoning (Blair, 1999; Blair, Monson, & Frederickson, 2001; Dolan & Fullam, 2010). Furthermore, several studies have shown that antisocial youth high on CU traits endorse more deviant values and goals in social situations, such as viewing aggression as a more acceptable means for obtaining goals, blaming others for their misbehavior, and emphasizing the importance of dominance and revenge in social conflicts (Chabrol, Van Leeuwen, Rodgers, & Gibbs, 2011; Pardini et al., 2003; Stickle et al., 2009). On a laboratory task measuring altruistic behavior, adolescents scoring high on conduct problems and CU traits were more likely than controls were to make decisions that benefited themselves while harming others (Sakai, Dalwani, Gelhorn, Mikulich-Gilbertson, & Crowley, 2012).

Perhaps the most striking cognitive characteristics of children with CD and CU traits are found in their emotional learning of the valence of objects and actions following experiences with reinforcement and punishment. In particular, studies demonstrate that youth with high levels of CU traits perform poorly in learning tasks that require them to stop a previously rewarded response following a change in the reinforcement contingency, such that it comes to be progressively more associated with punishment (Fisher & Blair, 1998; O'Brien & Frick, 1996). Youth with CU traits also show impairments in reversal learning, involving learning to reverse the response associated with a stimulus following a change in the reinforcement contingency (Blair, Monson, & Frederickson, 2001; Budhani & Blair, 2005). These studies suggest that youth with CU traits are not simply unresponsive to punishment, as offered by early explanations for psychopathy (Lykken, 1995); more specifically, they have difficulties in reversal learning tasks involving both rewards and punishments (Budhani & Blair, 2005). Performance on these reversal learning tasks is thought to reflect the role of the orbitofrontal cortex in representing the value of the newly correct response, and this value representation should successfully guide the individual's decision making (Bechara, Damasio, & Damasio, 2000). However, the appropriate recruitment of the orbitofrontal cortex in the representation of reinforcement information may be disrupted in youth with CU traits, as suggested by findings that they show atypical orbitofrontal responses during reversal learning tasks (Finger et al., 2008).

Deficits in responding to social cues critical for moral socialization (i.e., others' distress) and in specific forms of emotional learning (i.e., stimulus–reinforcement learning) are believed to interfere with the efficient socialization of individuals with elevated CU traits (Blair, 2007; Frick & Morris, 2004). This interference is thought to underlie the deficits reported in the moral judgments made by children and adolescents with CU traits (Blair, 1999). Moreover, it probably contributes to their increased propensity to show positive outcome expectancies within aggressive situations with peers. As a result, children with CU traits are less likely to be capable of cognitively representing the negative consequences of the victims' distress.

Biological Correlates

As suggested by the behavior genetic studies reviewed previously, biological correlates also tend to be more strongly associated with childhood-onset CD; however, the types of biological correlates differ according to the presence–absence of significant levels of CU traits (Frick & Viding, 2009). Furthermore, these biological correlates tend to support the emotional and cognitive differences between groups of children and adolescents with CD that have been highlighted above. Specifically, research on psychophysiological correlates of CU traits supports the finding that children and adolescents scoring high on CU traits show blunted emotional reactivity to certain types of stimuli. For example, both Anastassiou-Hadjicharalambous and Warden (2008) and de Wied, van Boxtel, Matthys, and Meeus (2012) reported that youth with CD and CU traits showed a lower magnitude of heart rate change to emotionally evocative films, compared to youth with CD but normative levels of CU traits. Moreover, CU traits were negatively related to skin conductance reactivity during responses to peer provocation in a sample of detained

adolescent boys (Kimonis et al., 2008). Finally, children with CU traits have shown blunted cortisol reactivity to experimentally induced stress (Stadler et al., 2011).

To date, there have been three functional imaging studies of children and adolescents with high levels of CU traits. Two of these studies reported that youth with conduct problems and CU traits exhibited less right amygdala activity in response to fearful faces than controls did (Jones, Laurens, Herba, Barker, & Viding, 2009; Marsh et al., 2008). A third imaging study reported that youth with conduct problems and CU traits demonstrated abnormal responses within the ventromedial prefrontal cortex during punished reversal errors, compared to typical controls (Finger et al., 2008). These studies hold promise for potentially clarifying the neurological markers of some emotional and cognitive characteristics that distinguish children and adolescents with CU traits.

Traditionalism

A clear conclusion from this review of dispositional risk factors related to the development of severe conduct problems is that the extant research consistently suggests that most of these risk factors are more strongly related to childhood-onset than adolescent-onset CD. There is, however, one notable exception. Youth with adolescent-onset conduct problems show personality traits that endorse less traditional values, such as viewing societal rules and status hierarchies as less important (Dandreaux & Frick, 2009; Moffitt et al., 1996), and they are more rebellious, such as desiring more autonomy from parents, compared with the childhood-onset type (Piquero & Brezina, 2001). These personality features may increase the likelihood of inappropriate attempts to achieve autonomy (i.e., antisocial behavior) in adolescence that characterize the adolescent-onset group (Dandreaux & Frick, 2009).

Contextual Risk Factors

Prenatal and Early Childhood Factors

Several risk factors present early in life are associated with the development of conduct problems. Some research suggests that risk factors for future conduct problems can be identified in the mother during pregnancy or shortly after birth (Petitclerc, Boivin, Dionne, Zoccolillo, & Tremblay, 2009). For example, maternal prenatal cigarette smoking is a factor consistently associated with childhood conduct problems; however, it is not clear to what extent comorbid ADHD or the transmission of an underlying antisocial tendency from mother to child accounts for this association (D'Onofrio et al., 2010; Latimer et al., 2012; Murray, Irving, Farrington, Colman, & Bloxsom, 2010). Other risk factors that are associated with ODD or CD when they occur during the prenatal period or in the first 5 years of life include alcohol use, stress, and viral illness in the mother during the prenatal period; lead exposure; malnutrition; and adoption (Barker & Maughan, 2009; Marcus, Fulton, & Clarke, 2010; Murray et al., 2010; Petitclerc et al., 2009). The extent to which genetic factors contribute to a child's exposure to these early risk factors is not clear, however, since a parent may transmit an externalizing liability to the child that both places the child at risk for conduct problems and puts the parent at risk for engaging in impulsive and antisocial behaviors and substance abuse (Markon & Krueger, 2005).

Familial Factors

A host of risk factors within the family have been associated with ODD and CD, including low socioeconomic status (SES), parental separation, and maternal depression (Averdijk, Malti, Eisner, & Ribeaud, 2012; Goodman et al., 2011; Lavigne et al., 2012). High rates of family stress and conflict can also lead to the development of conduct problems, with ongoing stress contributing to the stability of ODD (Lavigne et al., 2011, 2012). These factors may also interact with (i.e., moderate) other risk factors in the development of conduct problems. For example, in preschoolers with symptoms of hyperactivity, maternal depression predicted the later development of ODD (Harvey, Metcalfe, Herbert, & Fanton, 2011). The association between risk factors and conduct problems may also be mediated by other, more proximal risk factors, as indicated by a study of 4-year-old community children ($N = 796$; Lavigne et al., 2012). In this study, the effect of low SES on ODD symptoms was mediated by family stress and conflict, parental depression, and parental hostility toward/lack of emotional support to a child. Furthermore, stress and conflict influenced parental depression and dysfunctional parenting, which in turn affected ODD symptoms.

The most central and consistent family influence on the development and maintenance of conduct problems is that of dysfunctional parenting practices. Across a

large number of studies, lack of parental involvement, poor monitoring and supervision, low parental warmth, failure to use positive reinforcement, high parental hostility, and the use of harsh and inconsistent discipline have been linked to the development of ODD and CD (Chamberlain, Reid, Ray, Capaldi, & Fisher, 1997; Frick, 2006; Loeber & Stouthamer-Loeber, 1986; Patterson, 1996). Importantly, dysfunctional parenting often mediates the association between other contextual factors (e.g., poverty, maternal depression, high rates of family conflict) and childhood conduct problems (see, e.g., Lavigne et al., 2011). For example, Shaw, Hyde, and Brennan (2012) found that low-income 18-month-old boys exposed to high levels of dysfunctional parenting and maternal depression were at high risk for a trajectory of early-starting and increasing antisocial behavior to age 17. Thus it is quite possible that many contextual factors have their influence on childhood conduct problems by affecting parents' ability to use effective parenting strategies to socialize their children adequately.

Failures in parental socialization of their children play a role in many theories developed to explain the etiology of childhood conduct problems (e.g., Patterson, 1996). However, as with other risk factors, the role it plays may vary across the different developmental pathways. Specifically, although several studies have reported results showing that children in the childhood-onset subgroup tend to come from homes with greater levels of family instability, with more family conflict, and with parents who use less effective parenting strategies (Aguilar, Sroufe, Egeland, & Carlson, 2000; McCabe, Hough, Wood, & Yeh, 2001; Patterson & Yoerger, 1997; Woodward, Fergusson, & Horwood, 2002), parenting factors have played an important role in theories for the development of adolescent-onset CD as well. For example, poor parental supervision and low parental involvement, especially when combined with association with deviant peers, are often viewed as being critical to the processes that lead some adolescents to be more rebellious than is normative (Moffitt, 2006; Patterson & Yoerger, 1997). For the childhood-onset type without CU traits, conduct problems are viewed as resulting from an interaction between a child's risky temperament (e.g., impulsivity, poorly regulated emotions) and exposure to a problematic socializing environment (e.g., ineffective parental discipline). This interaction disrupts the socialization of the child and leads to enduring vulnerabilities and adjustment problems across the lifespan (Patterson, 1996).

Risky temperaments are likely to originate from genetic predispositions; however, neither genetic vulnerabilities nor environmental risk factors are sufficient in themselves for the development of conduct problems. Rather, mounting evidence suggests that gene–environment interactions play an important role. For example, Lahey and colleagues (2011) found that 4- to 6-year-old children meeting diagnostic criteria for ADHD who were exposed to more negative and less positive parenting practices in early childhood showed greater CD symptoms several years later when they possessed two copies of the 9-repeat allele of the variable-number tandem repeat (VNTR) polymorphism in the 3′ untranslated region (UTR) of the dopamine transporter gene (DAT1), compared to children without this polymorphism. Similarly, Edwards and colleagues (2010) found that community-based men exposed to childhood physical discipline who carried a low-activity risk allele at the promoter region (uVNTR) of the MAOA gene, which is located on the X chromosome, were more likely to engage in delinquent behavior later in life than were males not carrying the risk allele. While children exposed to physical discipline were generally more likely to engage in delinquency, those with the polymorphism in the absence of physical discipline were not. Other studies of gene–environment interaction identify the polymorphism at the COMT Val-158Met, which is also involved in regulating dopamine levels (Albaugh et al., 2010). Together, these studies suggest that ineffective and harsh parenting interacts with a child's genotype to influence the development of conduct problems (see Dodge, 2009).

The extent to which gene–environment interactions relate to the development of conduct problems in children with CU traits is less well understood. Moreover, the role of parenting in the development of conduct problems appears to be quite different for children with CU traits. Specifically, research consistently demonstrates that harsh, inconsistent, and coercive discipline is more highly associated with conduct problems in youth scoring low on CU traits (Edens, Skopp, & Cahill, 2008; Hipwell et al., 2007; Oxford, Cavell, & Hughes, 2003; Pasalich, Dadds, Hawes, & Brennan, 2012; Wootton, Frick, Shelton, & Silverthorn, 1997; Yeh, Chen, Raine, Baker, & Jacobson, 2011). In contrast, low warmth in parenting appears to be more highly associated with conduct problems in youth with CU traits (Kroneman, Hipwell, Loeber, Koot, & Pardini, 2011; Pasalich et al., 2012). Research also documents that dysfunctional parenting practices are related

directly to CU traits themselves (Barker et al., 2011; Waller et al., 2012). For example, in a prospective longitudinal study of a population-based sample (N = 7,000), harsh parenting at age 4 significantly predicted CU traits at age 13, accounting for 10% and 14% of the variance in these traits in boys and girls, respectively (Barker et al., 2011). However, the direction of influence between parenting practices and CU traits is not clear. In the few longitudinal studies that have tested potential bidirectional effects of parenting and child characteristics, CU traits have been more predictive of changes in parenting over time than parenting has been predictive of changes in CU traits over time (Hawes, Dadds, Frost, & Hasking, 2011; Muñoz, Pakalniskiene, & Frick, 2011).

Several studies report an association between CU traits and disorganized attachment styles (Bohlin, Eninger, Brocki, & Thorell, 2012; Fite, Greening, & Stoppelbein, 2008; Pasalich, Dadds, Hawes, & Brennan, 2011). Potentially related to the problems in attachment, Dadds, Jambrak, Pasalich, Hawes, and Brennan (2011) reported that children with high levels of CU traits made less eye contact with both mothers and fathers in free-play and "emotional talk" scenarios. In a second study, Dadds, Allen, and colleagues (2012) reported that children with conduct problems and CU traits also showed lower levels of physical and verbal affection, and made less eye contact with mothers during a task where the mothers said they loved their children and showed affection, compared to controls and children with conduct problems but without CU traits. Together, these studies led Dadds, Allen, and colleagues to suggest that a deficit in the propensity to make eye contact with an attachment figure "signals the absence of a basic building block underlying social and moral development" in children with non-normative levels of CU traits (p. 195).

Peer Relationships

Children and adolescents with ODD and CD often have problems in their peer relationships. The two most common problems are peer rejection (i.e., they have few friends and their peers actively dislike them; Dodge, Bates, & Pettit, 1990; Price & Dodge, 1989) and affiliation with deviant peers who show high levels of antisocial behavior (McCabe et al., 2001). It is less clear, however, whether these problems are differentially associated with the various developmental pathways discussed in this chapter. For example, some studies have found that youth in the adolescent-onset group have more deviant peer associations than youth in the childhood-onset group (McCabe et al., 2001), whereas other researchers have not found such differences (Dandreaux & Frick, 2009; Fergusson et al., 1996; Moffitt et al., 1996, 2002; Patterson & Yoerger, 1997). Furthermore, compared with youth scoring low on CU traits, adolescents with high levels of CU traits may be more likely to commit crimes in groups and show the highest level of association with delinquent and antisocial peers (Goldweber, Dmitrieva, Cauffman, Piquero, & Steinberg, 2011; Kimonis, Frick, & Barry, 2004; Muñoz, Frick, et al., 2008; Pardini & Loeber, 2008).

Thus problems in peer relationships (particularly association with a deviant peer group) may play a role in both childhood-onset and adolescent-onset conduct problems, and in conduct problems with and without non-normative levels of CU traits. However, the developmental processes linking the problematic peer relationships may differ across the different subgroups. For example, many theories consider association with a deviant peer group as being a critical causal process to the adolescent-onset group, with the peer group encouraging and supporting the youth's misguided attempts to achieve autonomy (Moffitt, 1993, 2006; Patterson & Yoerger, 1997). For those in the childhood-onset group (i.e., without CU traits), their problems in emotional and behavioral dysregulation and associated cognitive biases can place the youth at risk for rejection by conventional peers, depriving them of important peer socializing experiences that foster the development of social and cognitive skills (Dodge et al., 1990; Price & Dodge, 1989). Rejection by conventional peers may cause children to seek out associations with nonconventional and deviant peers, particularly when parents provide poor supervision (Coie, Terry, Zakriski, & Lochman, 1995; Dishion, Patterson, Stoolmiller, & Skinner, 1991; McCabe, Rodgers, Yeh, & Hough, 2004; Vitaro, Brendgen, Pagani, Tremblay, & McDuff, 1999).

The potential roles of peer rejection and delinquent peer affiliations for those children and adolescents with CU traits have been the subject of much less research. In one of the few studies of the friendships of youth with CU traits, Muñoz, Kerr, and Besic (2008) reported that in a population-based sample (N = 667) of adolescents (ages 12–15), those with CU traits had as many friends as other adolescents; however, the friendships were less stable and were viewed by the youth high on CU traits as more conflictual. Although the study by Muñoz and colleagues did not examine conduct

problems specifically, Kimonis and colleagues (2004) did; they similarly found that community boys and girls scoring high on CU traits and conduct problems reported having friends, but that their friends tended to be more delinquent than were the friends of youth with CU traits or conduct problems alone. Kerr, Van Zalk, and Stattin (2012) used peer network analyses to test the effects of both the target adolescents' levels of CU traits and their peers' levels of CU traits on the association between antisocial peers and delinquency. Their findings suggest that the delinquent behavior of the target adolescents was less influenced by peer delinquency if they scored high on CU traits. However, if an adolescent had friends who had high levels of CU traits, his or her delinquent behavior was more influenced by their peer delinquency. These findings raise the provocative possibility that the antisocial behavior of the adolescents with CU traits may be less likely to be caused by deviant peers, but that these adolescents may have a strong influence on the antisocial behavior of their peer group.

There is a well-established link between conduct problems and bullying (Crapanzano, Frick, Childs, & Terranova, 2011). ODD and CD are among the most common psychiatric disorders diagnosed in children involved in bullying, particularly those who are also victimized (i.e., "bully-victims"; Kumpulainen, Räsänen, & Puura, 2001). "Bullying" is defined as repeated physical, verbal, or psychological attack or intimidation that is intended to cause fear, distress, or harm to the victim; that occurs within particular interpersonal relationships; and that is characterized by an imbalance of power (Olweus, 1993). It has been described as a form of proactive aggression that involves achieving dominance over peers through intimidation in order to "construct, promote and/or reinforce [a] grandiose self-image" (Washburn, McMahon, King, Reinecke, & Silver, 2004, p. 256). However, youth who engage in bullying behaviors exhibit both proactive and reactive aggression (Camodeca et al., 2002; Salmivalli & Nieminen, 2002). Adolescents with conduct problems who also score high on CU traits are at particularly high risk for bullying. For example, Viding, Simmonds, Petrides, and Frederickson (2009) found that the combination of conduct problems and CU traits predicted greater rates of bullying than either condition alone, among a large (N = 704) sample of young adolescents (ages 11–13 years). Furthermore, CU traits contributed to the statistical prediction of peer-reported bullying, over and above the variance accounted for by conduct problems. In another study capturing a broader adolescent range (ages 12–18 years; M = 14.63 years), CU traits were strongly associated with bullying in Greek Cypriot youth (N = 347; Fanti, Frick, & Georgiou, 2009). Using a longitudinal study design, Fanti and Kimonis (2012) found that adolescents (N = 1,416) with conduct problems and CU traits were at greatest risk for engaging in bullying behaviors across development, compared with those youth exhibiting low or moderate levels of CU traits or conduct problems alone. Together, this research suggests that CU traits, alone or in combination with conduct problems, are associated with greater risk for engaging in bullying.

Neighborhood Characteristics

Children living in dangerous neighborhoods are at risk for developing conduct problems. Within the United States, neighborhood quality and ethnicity are usually confounded because minorities tend to be overrepresented in impoverished neighborhoods. Poor neighborhood quality exposes youth to peers and other individuals with antisocial attitudes and behaviors. Exposure to community violence, which is also common in impoverished neighborhoods, is robustly associated with conduct problems (Cooley-Strickland et al., 2009). Furthermore, the risk for negative child outcomes increases as the violence becomes more physically proximal, with the poorest outcomes for youth directly victimized by violence (P. J. Fowler, Tompsett, Braciszewski, Jacques-Tiura, & Baltes, 2009). Poor neighborhood quality and the stress associated with it may also affect the quality of parenting by causing parents to be more restrictive and harsh, in an effort to keep children under control and protected from negative outside influences (see Campbell, Shaw, & Gilliom, 2000).

Protective Factors

A variety of protective factors have been identified to explain why many children with ODD do not progress to CD, or why adolescents with CD do not progress to antisocial personality disorder in adulthood. More generally, an entire field of resilience research has emerged to explain why children with environmental and/or genetic vulnerabilities do not develop psychopathology (Garmezy, Masten, & Tellegen, 1984). In many cases, protective factors are the opposite of risk factors; for instance, positive parenting operates as a protective factor, and dysfunctional parenting operates as a risk

factor (Burke, Loeber, & Birmaher, 2002). Protective factors buffer the impact of risk factors on children and are often examined by testing whether these factors interact (i.e., moderate) to predict antisocial outcomes. For example, family support interacted with neighborhood disorder to predict antisocial behavior, such that Mexican American (n = 673) and African American (n = 897) children living in dangerous or disadvantaged neighborhoods (i.e., risk factor) showed fewer antisocial behaviors when exposed to higher levels of family support (i.e., protective factor) (Schofield et al., 2012). Protective or resilience factors fall into three primary categories: external societal support systems (e.g., good schools), positive dispositional characteristics (e.g., good cognitive and socioemotional skills), and a nurturing family milieu (e.g., high-quality relationships with parents and other adults) (Masten et al., 1999). Later in development, factors that serve to disconnect individuals from earlier negative influences and provide them with new opportunities in adulthood (e.g., military service, marriage) may protect socially disadvantaged antisocial youth from showing behaviors that persist into adulthood (see Rutter, 2012).

Although there has been relatively little study of protective factors in relation to conduct problem subtypes, maternal support or responsiveness and secure child attachment, which are important protective factors against the development of conduct problems generally (Shaw et al., 2003), may be particularly relevant to the development of CU traits. Research investigating the effects of certain parenting practices indicates that practices not relying solely on punishment-related arousal for internalization of parental norms, but instead focusing on the positive qualities of the parent–child relationship, are more effective in promoting conscience development in relatively fearless children (Kochanska, 1997). Similarly, in a longitudinal study, Pardini and colleagues (2007) found that children exposed to warm and involved parenting showed a reduction in CU traits 1 year later. Thus, warm and involved parenting may buffer against the development of CU traits, in particular among children with risky fearless temperaments. These examples illustrate the importance of testing potential protective factors that can enhance the development of children who may show some of the temperamental risk factors for severe conduct problems. They also suggest that integrating research on normative conscience development with research on children with conduct problems (i.e., a developmental psychopathology perspective) may permit researchers to examine which protective factors might deflect children from this particularly severe and stable course of deviant behavior.

AN OVERARCHING THEORETICAL FRAMEWORK FOR POSSIBLE DEVELOPMENTAL PATHWAYS

Taken together, the many factors associated with the development of conduct problems, combined with the evidence supporting distinct subgroups of youth, lead to a comprehensive and integrative model for understanding the different developmental pathways through which children may develop severe conduct problems (Frick & Viding, 2009). The first pathway supported by this research is the adolescent-onset pathway, in which CD symptoms coincide with the onset of puberty. Children in this pathway show fewer dispositional risk factors, and the developmental mechanism involved seems to be an exaggeration of the normative process of adolescent rebellion and identity formation, rather than an enduring vulnerability. Some level of rebellious behavior is normative in adolescence as part of the typical development of identity. However, youth with adolescent-onset CD are likely to experience factors that lead to a more severe and impairing pattern of rebellion than is typical. Such factors could include association with a deviant peer group, poor supervision by parents, or personality traits characterized by a rejection of traditional status hierarchies.

Children within the childhood-onset pathways show more biological, emotional, cognitive, and contextual risk factors than those in the adolescent-onset group. However, within the childhood-onset pathway, there appear to be important differences between those who do and who do not show elevated CU traits. Those who show normative levels of CU traits are more likely to show deficits in verbal abilities, which, combined with inadequate socializing experiences, could result in problems in the executive control of behavior (such as an inability to anticipate the negative consequences of inappropriate behavior or an inability to delay gratification). Also, the cognitive (e.g., hostile attributional biases) and emotional (e.g., heightened reactivity to negative stimuli) characteristics of children in this group, again combined with inadequate socializing experiences, could lead to problems in regulating emotion. These problems in emotional regulation could result in the children's committing impulsive and unplanned

aggressive and antisocial acts for which they may be remorseful afterward. This dysfunctional transactional process disrupts the children's socialization, leading to poor social relations with persons both inside (e.g., parents and siblings) and outside (e.g., peers and teachers) their families.

Finally, although youth with CU traits (labeled as CD "with limited prosocial emotions" in DSM-5) appear to constitute a minority of those within the childhood-onset group, they show a particularly severe, stable, and aggressive pattern of conduct problems (see Figure 3.1). This group seems to show a distinct temperamental style that places them at risk for missing some of the early precursors to empathic concern, and that may make these children relatively insensitive to the prohibitions and sanctions of parents and other socializing agents. It can lead to problems in the development of conscience, whereby the children become so focused on the potential rewards and instrumental gains of aggression or other antisocial means to solve interpersonal conflicts that they ignore the potentially harmful effects of this behavior on themselves and others.

CURRENT ISSUES AND FUTURE DIRECTIONS

This approach to conceptualizing the development of severe conduct problems has a number of important implications for future research that could advance our understanding of the causes of ODD and CD and improve the assessment, prevention, and treatment of these disorders (Frick, 2012). It is not sufficient for research simply to focus on documenting which risk factors are associated with these disorders or which risk factors account for the most or the most unique variance in measures of antisocial behavior, aggression, or delinquency, since such approaches assume that ODD and CD are unitary outcomes. That is, a variable may be related to the symptoms of CD or may differentiate between children with and without CD in the overall sample; however, this overall association may obscure the fact that it is only related to the behavior of a subgroup of youth with CD. Illustrating this point, dysfunctional/ineffective parenting showed a moderate but significant association with conduct problems in one study after the researchers controlled for several demographic variables; however, this overall association obscured a highly significant positive association for children scoring low on CU traits, versus a weak and nonsignificant negative association for those scoring high on CU traits (Wootton, Frick, Shelton, & Silverthorn, 1997).

A key component to the developmental models outlined in this chapter relates to the different temperamental predispositions (e.g., fearlessness and low behavioral inhibition; high levels of emotional reactivity) and related neurological systems (e.g., reduced amygdala responses; abnormal responses of the orbitofrontal cortex) that may place a child at risk for manifesting severe conduct problems. However, the vast majority of research has focused on children and adolescents who already show severe and impairing conduct problems. Therefore, it will be critical for future research to study children with the hypothesized temperamental and/or biological risk factors early in life, to determine how well these factors predict later severe antisocial behavior. Such longitudinal research is not only important for providing strong tests of the predictive utility of the developmental model; it could also identify protective factors reducing the likelihood that a child with a temperamental risk factor will develop severe conduct problem behaviors. For example, children who display a fearless and uninhibited temperament may show enhanced conscience development and, as a result, lower levels of conduct problems, if they are exposed to consistent, strong, and warm parenting (Cornell & Frick, 2007; Kochanska, 1997; Kochanska & Murray, 2000).

Although there have been many studies showing different correlates to the different conduct problem pathways, there have been far fewer studies directly comparing the specific biological vulnerabilities across subgroups. Future research comparing biological vulnerabilities across the developmental pathways could help to document how the genetic vulnerability to severe conduct problems might lead to the various cognitive and emotional deficits displayed by youth with ODD and CD. For example, Frick and Viding (2009) reviewed molecular genetic studies suggesting that the MAOA low-activity risk polymorphism may relate specifically to children who show primarily impulsive and reactive types of conduct problems. Furthermore, they reported that other studies have identified an increased vulnerability to antisocial behavior in the presence of the MAOA high-activity allele (e.g., Manuck, Flory, Ferrell, Mann, & Muldoon, 2000). Thus it is possible that different alleles of the same gene may predispose youth to different conduct problem pathways by having opposite effects on affective lability.

Given that conduct problems are related to both genetic and environmental risk factors, twin and adoption

studies offer another promising research methodology for investigating various types of gene–environment correlations and interactions. For example, risk factors that have been traditionally conceptualized as environmental (e.g., parenting practices) may actually be evoked partly by children's heritable temperamental features (gene–environment correlation; Larsson, Viding, Rijsdijk, & Plomin, 2008). Moreover, there may be genetically influenced individual differences in the sensitivity to environmental risk factors such as maltreatment (gene–environment interaction). For example, the genetic vulnerability to CD conferred by the MAOA low-activity allele may only manifest itself in the presence of an environmental trigger such as maltreatment (Caspi et al., 2002; Kim-Cohen et al., 2006). Unfortunately, possible unique gene–environment correlations or interactions across each of the different developmental pathways to conduct problems have not been examined to date.

Research on the different developmental pathways to ODD and CD could have important implications for preventing and treating severe conduct problems in children and adolescents. One key implication of this approach is the importance of prevention. As noted previously, the most aggressive youth, and the youth most likely to continue their antisocial behavior into adulthood, tend to show a childhood onset to their behavior. Furthermore, several interventions have proven effective in treating early-emerging conduct problems, but have shown a great decrease in their effectiveness with older children and adolescents (Eyberg, Nelson, & Boggs, 2008; McMahon et al., 2006). Another implication from this research on the developmental pathways to conduct problems is that no risk factor—whether genetic, temperamental, or environmental—operates in isolation. Thus it is not surprising that some of the most effective interventions for severe conduct problems involve multiple components, rather than targeting only a single risk factor (e.g., Conduct Problems Prevention Research Group, 2010). Perhaps the most important implication of this research on developmental pathways for treatment is that optimal interventions for children and adolescents with ODD and CD must not only be comprehensive; they also need to be tailored to each child's and family's individual needs, which are likely to differ depending on the specific mechanisms underlying the child's behavioral disturbance. As a result, some of the most effective treatments for older children and adolescents with CD are comprehensive and individualized interventions (Burns et al., 2003; Butler, Baruch, Hickey, & Fonagy, 2011; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 2009).

Research on the different developmental pathways to conduct problems has great potential for informing these individualized approaches to treatment (Frick, 2012). For example, the most effective interventions for youth in the adolescent-onset pathway are likely to be somewhat different from the most effective interventions for other youth with CD. Specifically, interventions focusing on enhancing identity development in adolescents and increasing contact with prosocial peers, such as mentoring programs (Grossman & Tierney, 1998) or programs that provide structured afterschool activities (Mahoney & Stattin, 2000), may be particularly effective for youth within the adolescent-onset pathway. In contrast, interventions that focus on anger control (Larson & Lochman, 2002) or on reducing harsh and ineffective parenting (e.g., Forgatch & Patterson, 2010; McMahon & Forehand, 2003) may be more effective for children within the childhood-onset pathway who do not exhibit elevated CU traits, but who often show problems with emotional regulation and come from families that employ dysfunctional parenting practices (see McMahon & Pasalich, in press, for a review).

Given that shared genetic factors contribute to ODD/CD and ADHD, which is highly heritable (Faraone et al., 2005; Faraone & Mick, 2010), early intervention with children diagnosed with ADHD appears important to preventing the later development of ODD and perhaps CD. The best-supported intervention for children with ADHD is medication management with or without behavioral treatment (MTA Cooperative Group, 1999, 2004), such as parent management training. Such medications may not only reduce the inattentive and impulsive behavior of ADHD that feeds forward into ODD and CD risk, but may particularly improve the emotional impulsivity and poor emotional self-regulation associated with ADHD (Barkley, 2010). Similarly, the failure to treat comorbid ADHD among children with ODD or CD may predict poorer treatment response.

Finally, interventions emphasizing reward-oriented approaches that target youth's self-interests (rather than punishment-based approaches), and that increase parental warmth and involvement, may be more effective for children with CU traits (Caldwell, Skeem, Salekin, & Van Rybroek, 2006; Dadds, Cauchi, Wimalaweera, Hawes, & Brennan, 2012; Somech & Elizur, 2009). The important advances that have been made in in-

corporating the different developmental pathways into current diagnostic classification systems are critical to encouraging continuing research and the testing of innovative interventions for youth on different developmental pathways to childhood and adolescent conduct problems.

CHAPTER 4

Adolescent Substance Use Disorders

LAURIE CHASSIN
KAITLIN BOUNTRESS
MOIRA HALLER
FRANCES WANG

Adolescent substance use and substance use disorders (SUDs) are topics of clinical and public health concern because of their prevalence and associated negative consequences. There are also substantial economic costs. Considering all age groups, recent estimates suggest costs in the United States of $193 billion for tobacco use (Centers for Disease Control and Prevention, 2008), $223 billion for excessive alcohol use (Bouchery, Harwood, Sacks, Simon, & Brewer, 2011), and $193 billion for the use of illegal drugs (National Drug Intelligence Center, 2011). Moreover, although many adolescents experiment without experiencing adverse consequences, adolescent substance use is associated with increased risk for all three of the leading causes of death in adolescence (accidents, suicide, and homicide), as well as increased risk for sexually transmitted disease and the development of clinical substance use disorder (Institute of Medicine, 1994; Moritsugu & Li, 2008). Although the magnitude, specificity, and durability of effects are unclear, there is also concern that adolescent substance use can impair emerging neurocognitive functioning (see Squeglia, Jacobus, & Tapert, 2009, for a review), as well as developmental competence and psychosocial functioning (Baumrind & Moselle, 1985; Chassin, Pitts & DeLucia, 1999; Chassin et al., 2010).

This chapter describes the features and epidemiology of adolescent substance use and SUDs, and examines etiological factors with an emphasis on recent evidence. The chapter is not intended to be comprehensive; for example, we do not consider issues of treatment or prevention. (For discussions of treatment, see Becker & Curry, 2008; Deas & Thomas, 2001; Hser et al., 2001; Liddle, 2004; and Waldron & Kaminer, 2004. For discussions of prevention, see Bukoski, 1997; Spoth, Greenberg, & Turrissi, 2008; Substance Abuse and Mental Health Services Administration [SAMHSA], 1999, 2000; and Winters, Fawkes, Fahnhorst, Botzet, & August, 2007.) Moreover, because many empirical studies consider only substance use, we include coverage of adolescent substance use as well as SUDs, while noting the distinctions between them. Finally, our discussion spans developmental periods ranging from early childhood precursors of adolescent SUDs to the period of "emerging adulthood" (ages 18–25), when SUDs reach their peak.

HISTORICAL CONTEXT

A historical perspective on adolescent substance use and SUDs must be placed within the broader context

of historical changes in the definitions of adolescence. Prior to the 19th century, the transition from childhood to adulthood was short; after puberty children often gained many of the freedoms and responsibilities of adulthood, including substance use (Lender & Martin, 1987). However, as the American economy changed in the 19th century, adult occupations required greater training and maturity. Adolescence began to be viewed as a period that required moral instruction as well as preparation for the economic and social demands of adulthood. As adolescence became more strongly differentiated from adulthood, societal attitudes toward adolescent substance use became more negative (Lender & Martin, 1987).

Coincident with changes in attitudes toward adolescent substance use in 19th-century America was a rise in alcohol temperance movements that peaked with the Prohibition (1919–1933). Since then, societal movements against psychoactive substances have included movements against opiates in the early 20th century, marijuana in the 1920s, narcotics in the 1950s, and cocaine (including crack) in the 1980s (Bukstein, 1995).

The origins of the current "war on drugs" can be tied to the rise of the counterculture of the late 1950s and 1960s. This era brought increases in the use and social acceptance of many psychoactive drugs, particularly marijuana and LSD. As substance use became more common among middle-class American college students in the 1960s, there was increased societal concern about drug use and increased antidrug legislation. The Drug Abuse Control Amendment of 1965 and the Controlled Substances Act of 1970 brought hallucinogens, stimulants, and depressants under the regulatory control of the federal government, whereas before the 1960s only narcotics were controlled substances (Maisto, Galizio, & Connors, 1999). In the 1970s, national epidemiological studies were undertaken to monitor trends in adolescent substance use (e.g., the Monitoring the Future Study [MTF], to be discussed later, began in 1975). The "war on drugs" under Presidents Ronald Reagan and George H. W. Bush saw increases in federal funding of nearly 700% for federal drug programs, the appointment of a federal "drug czar," and increased military activity to counter drug supply (Humphreys & Rappaport, 1993). Societal conceptualizations of and attitudes toward adolescent substance use continue to evolve today, with recent trends including increases in the legal drinking age, controversies over medical marijuana laws, a reconceptualization of tobacco use as an addictive behavior, and U.S. Food and Drug Administration regulation of tobacco products pursuant to the Family Smoking Prevention and Tobacco Control Act of 2009.

DEFINITIONAL AND DIAGNOSTIC ISSUES

Current Diagnostic Criteria

In the United States, the most commonly used diagnostic system is the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). At this writing, a new version has just been released, DSM-5 (American Psychiatric Association, 2013). One major change from DSM-IV (American Psychiatric Association, 1994) is the removal of the distinction between substance abuse and substance dependence, which have been replaced with a single diagnosis of SUD (which can be applied to alcohol; cannabis; hallucinogens; inhalants; opioids; sedatives, hypnotics, and anxiolytics; stimulants; and tobacco). The DSM-5 criteria for SUD include tolerance (needing greater amounts of a substance in order to become intoxicated, or experiencing reduced effects from the same amount of consumption); withdrawal (cognitive and physiological changes upon discontinuing the substance); taking the substance in greater amounts or over longer times than intended; giving up important activities because of use; unsuccessful attempts to cut down or a persistent desire to cut down on use; spending much time in obtaining, using, or recovering from using the substance; continuing to use the substance despite physical, psychological, social, or interpersonal problems that are being exacerbated by this consumption; failing to meet important obligations at home or school/work; and use in hazardous situations. A new symptom added for DSM-5 is craving, which is defined as a powerful urge or desire to use the substance; also, the DSM-IV substance abuse criterion of recurrent legal problems has been removed from DSM-5. In DSM-5, an SUD is diagnosed if two or more symptoms occur within a 12-month period (with two to three symptoms indicating mild disorder, four or five indicating moderate disorder, and six or more indicating severe disorder).

As in prior versions of the DSM, adolescent SUDs are diagnosed with the same criteria that are applied to adults. However, the empirical support for this practice has been questioned. Studies using DSM-IV criteria have reported a category of "diagnostic orphans" (i.e., adolescents who endorse one or two symptoms but do

not qualify for a substance-related diagnosis, despite problematic use). Rates of these diagnostic orphans are substantial. For example, in studies of adolescents who regularly use alcohol, these rates have ranged from 13 to 30% (Harrison, Fulkerson, & Beebe, 1998; Lewinsohn, Rohde, & Seeley, 1996; Pollock & Martin, 1999). However, some recent data suggest that individuals who are categorized as "diagnostic orphans" by DSM-IV criteria will be likely to meet criteria for alcohol (Agrawal, Heath, & Lynskey, 2011) or marijuana (Mewton, Slade, & Teeson, 2013) disorder, according to the new DSM-5 criteria.

There are several reasons why recent diagnostic criteria (both DSM-IV and DSM-5) may be inadequate for adolescents. First, because adolescents are just beginning consumption, it is more normative for adolescents than for adults to show increases in tolerance (Martin, Steinley, Verges, & Sher, 2011; Winters, Martin, & Chung, 2011), so increased tolerance may not have the same meaning for the two age groups. Second, withdrawal is reported by a very small percentage of adolescents (Winters, 2013). Third, the hazardous use criterion may be less likely for adolescents because they have less access to motor vehicles (Martin, Sher, & Chung, 2011; Winters, 2013). In general, the degree to which criteria for SUDs capture (or fail to capture) the unique features of adolescents versus adults suggests that some modifications to adult classification systems might be necessary (Colby, Tiffany, Shiffman, & Niaura, 2000; Mikulich, Hall, Whitemore, & Crowley, 2001; Winters, Latimer, & Stinchfield, 1999). The possibility that the SUD diagnostic criteria are developmentally inappropriate when applied to adolescents may explain some findings that adolescents meet diagnostic criteria at lower levels of consumption than do adults (Langenbucher et al., 2000). However, because it has been reported that adolescents may be neurobiologically more sensitive to some of the effects of consumption (Adriani & Laviola, 2004; Spear, 2011), a greater neurobiological vulnerability might also lead adolescents to meet diagnostic criteria at lower levels of use compared to adults.

Given the overlap between DSM-IV and DSM-5 symptoms, many of the concerns that were raised with respect to diagnosing adolescent SUDs in DSM-IV are also likely to apply to DSM-5, although combining substance abuse and dependence into a single SUD diagnosis is empirically supported for adolescents (Winters et al., 2011). In addition, the DSM-5 removal of the legal-problems symptom is likely to improve diagnosis for adolescents because this symptom has been thought to relate more to associated conduct problems than specifically to SUD. However, concerns for DSM-5 include the need for clear operationalization of craving (a new criterion) and concern about whether the two-symptom threshold for diagnosis will overdiagnose SUDs (Martin, Steinley, et al., 2011; Winters et al., 2011). Overdiagnosis may be particularly likely among adolescents compared to adults, given that tolerance is relatively normative and that adolescents report using in "larger amounts than intended" for reasons of social conformity in peer contexts (Martin, Steinley, et al., 2011).

Related Symptoms and Disorders

SUDs in adolescence are typically accompanied by a number of clinical and subclinical symptoms. Most notably, adolescents with SUDs are likely to show polydrug use (Roberts, Roberts, & Xing, 2007). The most frequently occurring combination is alcohol and marijuana, followed by alcohol and hallucinogens, although one recent study involving college students found that nearly 10% used alcohol in combination with prescription drugs (Deas, Riggs, Langenbucher, Goldman, & Brown, 2000; Martin, Kaczynski, Maisto, & Tarter, 1996; McCabe, Cranford, Morales, & Young, 2006). Among adolescents in general, there is support for a developmental sequence of substance use involvement—beginning with the use of "gateway drugs" (alcohol and nicotine), followed by marijuana, and then other illegal drugs (Kandel, Yamaguchi, & Chen, 1992).

Adolescents with SUDs are further characterized by functional impairment in numerous domains. They exhibit poorer academic achievement and higher rates of academic failure than either youth who do not use substances or those without SUDs (Haller, Handley, Chassin, & Bountress, 2010; Moss, Kirisci, Gordon, & Tarter, 1994; Tarter, Mezzich, Hsieh, & Parks, 1995). Adolescents with SUDs tend to associate with deviant peer groups; to engage in delinquent behaviors (Blackson et al., 1999; Branstetter, Low, & Furman, 2011; Fergusson, Boden, & Horwood, 2008; Hawkins, Catalano, & Miller, 1992) and risky sexual behaviors (Malow, Devieux, Jennings, Lucenko, & Kalichman, 2001); and to experience negative interactions with their parents (Kuperman et al., 2001; Mezzich et al., 1997).

One of the most consistent findings in the literature is that adolescent SUDs are often comorbid with DSM-IV disruptive behavior disorders (Costello, Mustillo,

Erkanli, Keeler, & Angold, 2003; Elkins, McGue, & Iacono, 2007; Wilens et al., 2010). Cohen and colleagues (1993) and Costello and colleagues (2003) found that at least half of adolescents with SUDs were also diagnosed with disruptive behavior disorders. Among those with diagnosed SUDs, odds ratios for diagnoses of disruptive behavior disorders have been reported from 0.4 to 30.7, with the larger odds ratios pertaining to conduct disorder (CD), as compared to attention-deficit/hyperactivity disorder (ADHD) or oppositional defiant disorder (ODD) (Costello et al., 2003; Fergusson, Horwood, & Lynskey, 1993; Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993). Although the relations between SUDs and conduct problems appear unique, the link between ADHD and SUDs is more controversial, and the effect of ADHD is often eliminated after the effect of CD is taken into account (Brook, Brook, Zhang, & Koppel, 2010; Costello, Erkanli, Federman, & Angold, 1999; Fergusson & Horwood, 1995; Fergusson, Horwood, & Ridder, 2007; Glass & Flory, 2011; Weinberg, Rahdert, Colliver, & Glantz, 1998). In fact, one group found that the relation between ADHD and substance use problems was fully mediated by CD symptoms (Brook et al., 2010). Others report that ADHD and CD interact to increase risk for SUDs in adolescence (Flory & Lynam, 2003). Still others suggest that those with the different types of ADHD are at differential risk for substance problems, with hyperactivity–impulsivity being uniquely related to substance problems over and above CD symptoms, and inattention not being related to substance problems (Elkins et al., 2007). Because adolescent substance use problems rarely occur in the absence of other disruptive problem behaviors, heavy adolescent substance use is often considered a specific manifestation of broader-based problem behaviors (Donovan & Jessor, 1985). Some suggest that adolescent SUDs are the culmination of a deviant developmental trajectory, manifested in childhood and early adolescence by behavioral undercontrol and by antisocial and oppositional behavior (King, Iacono, & McGue, 2004; Tarter, Sambrano, & Dunn, 2002; Tarter & Vanyukov, 1994).

The relation between SUDs and internalizing disorders is less clear. Some have found that depression, social anxiety, and generalized anxiety are related to the onset of adolescent substance use (Costello et al., 1999; King et al., 2004; Schneier et al., 2009), although separation anxiety may actually reduce the likelihood of onset (Kaplow, Curran, Angold, & Costello, 2001), perhaps by decreasing time spent away from parents and in peer contexts. Other studies have found that depression and anxiety occur with adolescent SUDs, but that the relations with depression are stronger (Fergusson et al., 1993; Kandel et al., 1997; King et al., 2004; Lewinsohn et al., 1993). There have also been reports of interactions among different forms of internalizing symptoms in predicting substance use. For example, Valentiner, Mounts, and Deacon (2004) found that among late adolescents with panic attacks, depression predicted substance use, but depression was not a significant predictor of substance use among those without panic attacks. Because some of these studies examined slightly older samples, the associations between substance use outcomes and emotional disorders may increase with age, and emotional disorders may be the result of continued substance use. Moreover, some studies suggest that associations between emotional disorders and substance use outcomes are stronger for females than for males, with the exception of social phobia (social anxiety disorder), for which the link is stronger for boys (e.g., Bukstein, Glancy, & Kaminer, 1992; Federman, Costello, Angold, Farmer, & Erkanli, 1997; Sung, Erkanli, Angold, & Costello, 2004; Tarter, Kirisci, & Mezzich, 1997; Whitmore et al., 1997; Wu, Goodwin, et al., 2010).

EPIDEMIOLOGY

Prevalence Rates

Several national epidemiological studies were launched in the 1970s to monitor trends in adolescent substance use prevalence over time. The Monitoring the Future Study (MTF) began in 1975 as a school-based survey of substance use among the nation's high school seniors, and is administered annually to over 45,000 students in 8th, 10th, and 12th grades in 435 schools nationwide (Johnston, O'Malley, & Bachman, 2000, 2001, 2002, 2005; Johnston, O'Malley, Bachman, & Schulenberg, 2006, 2008, 2012). The National Household Survey on Drug Abuse (NHSDA) has been conducted since 1971, and obtains information from over 70,000 civilians age 12 or older across the nation in face-to-face interviews (SAMHSA, 2000, 2001).

Because parents are likely to be unaware of their adolescents' substance use, epidemiological studies on adolescent use rely on the adolescents' self-reports. Indeed, parent and adolescent reports show low levels

of agreement (Cantwell, Lewinsohn, Rohde, & Seely, 1997; Fisher et al., 2006). A large literature has addressed the validity of adolescent self-reports, including their validation with biological measures (e.g., Dolcini, Adler, & Ginsberg, 1996; Dolcini, Adler, Lee, & Bauman, 2003; Murray, O'Connell, Schmid, & Perry, 1987), and these data suggest that self-reports can be valid if they are obtained under conditions of anonymity and privacy, and if there is minimal motivation to distort responses. Data suggest that self-administered questionnaires substantially improve reporting, compared to data obtained via interviewer-style questioning (Etter, Houzec, & Perneger, 2003; Rogers, Miller, & Turner, 1998).

Data from the MTF suggest that adolescent substance use is relatively common by the end of the 12th grade. For example, the MTF data from 2011 showed that 20.1% of 8th graders and 49.9% of 12th graders had used some illegal drug in their lifetimes (Johnston et al., 2012). Marijuana was the most frequently used illegal drug, with 12.5% of 8th graders and 36.4% of 12th graders reporting use in the past year (Johnston et al., 2012). The use of substances that are legal for adults (i.e., alcohol and tobacco) was even more common, with 70% of high school seniors having tried alcohol at least once, and 40% reporting drinking in the past month (Johnston et al., 2012). As of 2011, 40% of 12th graders had tried cigarettes, and approximately 20% were current smokers (i.e., within the last 30 days; Johnston et al., 2012). In regard to prescription drug use, 21.7% of 12th graders had ever used at least one such drug without a doctor's order (Johnston et al., 2012). The use of different drugs is highly interrelated in both epidemiological and clinical samples of adolescents (Clayton, 1992; Johnston et al., 2001; Kandel, Davies, Karus, & Yamaguchi, 1986; Single, Kandel, & Faust, 1974; Young et al., 2002). For example, the 1985 NHSDA data showed that 24% of those who reported any illicit drug use used more than one drug at the same time within the past year, and 43% had used alcohol along with an illicit drug (Clayton, 1992).

In addition to finding that substance use generally increases during adolescence, the MTF data also reveal interesting patterns of change in drug use over time. In general, adolescent substance use peaked in the mid-1970s and early 1980s, and then declined. Substance use increased again in the early 1990s, but has since leveled off. At this writing (2013), there are declining trends for cigarettes and alcohol, Ecstasy (MDMA), Oxycontin, and Vicodin. On the other hand, the past-year use of stimulant drugs (e.g., Adderall) without a doctor's order has steadily increased, reaching 6.5% among high school seniors in 2011 (Johnston et al., 2012). Other drugs have shown more nuanced increases and decreases in use over time. For example, past-year cocaine use among 12th graders peaked in the early/mid-1980s, showed dramatic declines between 1986 and 1992, and then began to increase again until 2000. Between 2000 and 2006, cocaine use leveled off, and it has decreased steadily since 2006 (Johnson et al., 2012). Past-year inhalant use for high school seniors peaked in the mid-1990s and declined until the early 2000s, at which time use increased slightly and then began to decline again (Johnston et al., 2012). Johnston and colleagues (2012) also note that as older drugs wane in popularity, new drugs replace them. For instance, LSD and methamphetamine showed an increase in the 1960s; and heroin, crack and other forms of cocaine, and phencyclidine made a comeback in the 1990s after being initially unpopular (Johnston et al., 2005). Moreover, sometimes the popularity of a specific drug revives after a period of low use. Johnston and colleagues (2001, 2005, 2012) suggest that the use of a particular drug makes such a comeback because knowledge of its risks and negative effects gets lost from the adolescent culture after a period of nonuse. This phenomenon has been called "generational forgetting."

Substantial numbers of adolescents who use alcohol or drugs also report some problems associated with their substance use. For example, Zoccolillo, Vitaro, and Tremblay (1999) found that among adolescents using alcohol more than five times, 70% of boys and 53% of girls reported experiencing at least one alcohol-related problem, and 20% of boys and 11% of girls reported three or more problems. Of those who had used other drugs more than five times, 94% of boys and 85% of girls reported at least one drug-related problem, and 68% of boys and 52% of girls reported three or more problems. Among adolescents ages 13–17, rates of diagnosable disorders are about 2–7% for alcohol use disorders and 3–9% for other drug use disorders (Fergusson et al., 1993; Kessler et al., 2012; Merikangas et al., 2010; Roberts, Roberts, & Xing, 2007, 2008). Among older adolescents and emerging adults (ages 17–20), rates are approximately 12–18% for alcohol use disorders and 4–11% for other drug use disorders (Cohen et al., 1993; Merikangas & McClair, 2012; SAMHSA, 2001; Young et al., 2002). In general, rates of SUDs rise throughout adolescence, peak during emerging adulthood, and then decline.

Demographic Correlates

Gender

Numerous studies have documented gender differences in substance use prevalence. That is, girls, compared to boys, use fewer types of drugs, use them with less frequency, and drink less alcohol in a single sitting (Johnston et al., 2000, 2002; Wallace et al., 2003). In the MTF data, 12th-grade males have reported substantially higher prevalence rates for the annual use of heroin, LSD, ketamine, hallucinogens, cocaine, steroids, and smokeless tobacco, as well as in the daily use of marijuana and alcohol. At younger grades, however, males and females show similar rates of drug use for many drugs, and females even have higher rates of annual use of inhalants, tranquilizers, and amphetamines in 8th grade. This pattern may reflect a developmental phenomenon, with accentuating gender differences emerging over the course of adolescence; or a cohort effect, with gender differences decreasing among more recent cohorts of adolescents. Support for both potential explanations has been found. For example, Cohen and colleagues (1993) and Johnston and colleagues (2008, 2012) found that gender differences for alcohol use disorders and for illicit drug use increased as individuals moved into late adolescence (17–20 years of age). In addition, Chen and Jacobson (2012) found that although females drank, smoked, and used marijuana more than males in early adolescence, males' substance use increased at a higher rate than females', culminating in their higher use by the end of adolescence and into adulthood. However, Wallace and colleagues (2003) found that 12th-grade boys drank alcohol and used marijuana more frequently than their female counterparts, but that the magnitude of these differences decreased from the 1990s into the 2000s.

In addition to differential prevalence rates, males and females may use drugs for different reasons. Indeed, younger females (under 15 years old) report higher levels of social enhancement and coping motives than do younger males, although this difference is reversed in older adolescents (18–19 years old; Cooper, 1994). In a study of individuals ages 16–22, females were more likely than males to report using drugs to lose weight, stay awake, lose inhibitions, stop worrying, and enjoy the company of friends (Boys, Marsden, & Strang, 2001). Comeau, Stewart, and Loba (2001) found in their sample of adolescents (mean age 15) that males were more likely to drink alcohol to conform. Studies of tobacco use have found that females report stronger weight regulation and anxiety reduction motives than do males, who are more likely to smoke to enhance self-confidence (Berlin et al., 2003; Grunberg, Winders, & Wewers, 1991; Piko, Wills, & Walker, 2007; Rose, Chassin, Presson, & Sherman, 1996; see also Amaro, Blake, Schwartz, & Flinchbaugh, 2001, for a review of drug use among adolescent girls, and White & Huselid, 1997, for a review of gender differences in adolescent alcohol use).

Socioeconomic Status

Adolescent drug use has also been associated with socioeconomic status (SES). Goodman and Huang (2012) found that among 12- to 18-year-olds, adolescents with more educated parents drank alcohol and smoked cigarettes less frequently than did those with less educated parents. In the MTF data, lower parent education was associated with greater illegal drug use in the middle school years, but not in the high school years (Johnston et al., 2008, 2012). These diminished differences may reflect differential school dropout as a function of parental education or substance use, or a developmental phenomenon, with use becoming equally common across SES levels by the end of adolescence (Johnston et al., 2008). They might also reflect a cohort effect, such that substance use is becoming more concentrated in less educated subgroups among more recent cohorts (as has been argued for cigarette smoking; Fiore, Newcomb, & McBride, 1993).

Weaker relations have been reported between adolescent substance use and other indicators of SES, including family income (Goodman & Huang, 2012; Parker, Calhoun, & Weaver, 2000) and subjective ratings of familial SES (Fawzy, Combs, Simon, & Bowman-Terrell, 1987). It has also been suggested that low SES increases risk for adolescent substance use only when poverty co-occurs with childhood behavior problems (Hawkins et al., 1992). Moreover, the relation between adolescent substance use and SES may also vary with different drugs. For example, with the rise in prevalence of crack cocaine in the early 1980s, lower-SES populations exhibited increases in cocaine use, while their higher-SES counterparts showed declining use. Although this trend ended in 1985, it illustrates how social and economic factors—in this case, the increased opportunity to acquire this cheaper form of cocaine—can influence the SES distribution for specific drugs.

One reason for the weak and inconsistent associations between SES and adolescent substance use is that

the association may be curvilinear, such that SES may only influence adolescent substance use at its extreme ends. Interestingly, both high- and low-SES neighborhoods have been linked with increased adolescent substance use. Research indicates that decreased parental availability and supervision (Luthar & Latendresse, 2005), increased financial resources (Hanson & Chen, 2007), increased achievement pressures (Luthar & Becker, 2002), and increased parental drinking (Chuang, Ennett, Bauman, & Foshee, 2005) may mediate the influence of neighborhood affluence on adolescent substance use, whereas the influence of neighborhood *disadvantage* may be mediated by decreased social cohesion (Duncan, Duncan, & Strycker, 2002), greater acceptance of substance use, lower perceived harmfulness of substance use (Lambert, Brown, Phillips, & Ialongo, 2004), decreased after-school supervision (Luthar & Latendresse, 2005), and increased peer drinking (Chuang et al., 2005).

Ethnicity

In regard to ethnic correlates of use, MTF data show that African American high school seniors have the lowest prevalence rates (lifetime, annual, monthly, and daily) for use of alcohol, cigarettes, and all illegal drugs, compared to non-Hispanic European American and Hispanic American high school seniors. In 6th and 8th grades, Hispanic American students report more use than do European Americans, but this difference reverses at 12th grade, when European Americans tend to have the highest rates of drinking and illegal drug use, compared to African American and Hispanic American adolescents (Johnston et al., 2008, 2012). Possible reasons for this crossover between Hispanic Americans and European Americans are the comparatively high dropout rate of Hispanics, which may diminish initial ethnic differences, and/or the findings that European Americans begin using drugs later in adolescence and eventually overtake the prevalence rates of Hispanic Americans (Johnston et al., 2000, 2008). Native American adolescents also show high rates of use (Plunkett & Mitchell, 2000; Wallace et al., 2003), although their levels of use vary by geographic location. By contrast, Asian American high school seniors report very low levels of drug use, although this trend may be mostly driven by the very low rate of drug use by Asian American females (Wallace et al., 2003).

Research on ethnic differences in diagnosed adolescent SUDs appears to be mixed. For example, Costello, Farmer, Angold, Burns, and Erkanli (1997) found that Native American adolescents had significantly higher odds of receiving an SUD diagnosis than did European American adolescents; however, Mitchell, Beals, Novins, Spicer, and the American Indian Service Utilization, Psychiatric Epidemiology, Risk and Protective Factors Project Team (2003) found that 15- to 24-year-old Native Americans showed extremely low levels of SUDs. Results from another large-scale study (Kandel et al., 1997) showed that European American and African American adolescents were more likely to be diagnosed with an SUD than were Hispanic adolescents (for reviews of ethnic differences in drug use, see Barrera, Castro, & Biglan, 1999; Kandel, 1995). However, others (Roberts, Roberts, & Xing, 2006) found that European American adolescents were most likely to be diagnosed with an SUD, and African American adolescents were least likely to be diagnosed, with Mexican American adolescents being in the middle in terms of risk.

It may also be that apparent ethnic differences in substance use may in part reflect ethnic differences in reporting bias. For instance, Bauman and Ennett (1994) found that when self-report data were validated against a biological measure of tobacco use, African American adolescents underreported their smoking, whereas European American adolescents overreported their smoking. However, recent work using larger and more ethnically heterogeneous samples has suggested that the validity of self-reports is comparable across ethnic groups (Brener et al., 2002; Wills & Cleary, 1997).

In addition to varying by ethnicity, adolescent substance use seems to vary across cultures. Specifically, the frequency of drunkenness and smoking is higher in most European countries and in Australia than in the United States (Kuntshe, Knibbe, Kuntsche, & Gmel, 2011); McMorris, Hemphill, Toumbourou, Catalano, & Patton, 2007; Piko, Luszczynska, Gibbons, & Tekozel, 2005). However, in one study, lifetime marijuana use was greater in the United States than in Australia (McMorris et al., 2007). Research has also documented that there is higher lifetime alcohol use in the Commonwealth of Puerto Rico than in the rest of the United States (Warner, Canino, & Colon, 2001). Therefore it appears that prevalence rates of adolescent substance use vary by substance across countries, continents, and cultures.

As these data illustrate, rates of adolescent substance use vary with gender, SES, and ethnicity. However, these conclusions may oversimplify a more complex

picture, in that prevalence rates may vary as a function of complex interactions among gender and ethnicity, and also as a function of type of substance (Griesler & Kandel, 1998). In addition, the correlated effects of ethnicity and SES are difficult to disaggregate. Moreover, the mechanisms underlying these demographic differences have not been well articulated, and methodological artifacts such as sampling and reporter biases may affect the results of these studies.

DEVELOPMENTAL COURSE AND PROGNOSIS

Both substance use and SUDs show systematic age-related patterns from adolescence to adulthood—patterns that have led some researchers to view SUDs as developmental disorders (Masten, Faden, Zucker, & Spear, 2008; Sher & Gotham, 1999). Substance use is typically initiated in adolescence, and there are multiple reasons why adolescents may be vulnerable to substance use initiation. Recent data suggest that adolescence as a developmental period is characterized by a gap between changes in dopaminergic reward systems (producing increases in sensation seeking and reward seeking beginning at puberty) and the slower and more gradual development of top-down cognitive control, correlated with increased myelination both within prefrontal cortex and between cortical and subcortical areas (Steinberg, 2008). In addition, adolescence is characterized by greater time spent in peer activities beyond the supervision of parents, and the presence of peers has been shown to activate the same reward centers that lead to risky behavior (Chein, Albert, O'Brien, Uckert, & Steinberg, 2011). Finally, adolescents may be particularly vulnerable to substance use effects that make escalation of substance use particularly likely. For example, adolescents are more sensitive to some of the positive effects of substances, but less sensitive to some of the aversive effects (Spear, 2011).

Over the adolescent years, alcohol and drug use increase in quantity and frequency to reach a peak in the age period that Arnett (2000) has referred to as "emerging adulthood" (18–25 years of age). The prevalence of diagnosed SUDs also peaks in this age period (e.g., Grant et al., 1994). Then, in the mid- to late 20s, the consumption of alcohol and illegal drugs begins to decline. SUDs that decline in young adulthood have been referred to as "developmentally limited" (Zucker, 1987).

However, "maturing out" of substance use is likely to be more complex than originally proposed. For example, Lee, Chassin, and Villalta (2013) found that declines in drinking were not uniform, but rather were more common among individuals with heavier, problematic drinking than among those with other types of drinking, and that declines among those with heavy drinking reflected moderation rather than cessation of drinking. Verges and colleagues (2012) found that although persistence in DSM-IV alcohol dependence was somewhat lower in early adulthood than later in life, age-related declines in alcohol dependence were largely produced by reductions in new onset. Their findings suggest that alcohol dependence may be thought of as either "short-duration" or "chronic and episodic" (although "short-duration" alcohol use disorders may be more common at earlier ages).

Taking on adult roles in emerging adulthood has been thought to explain the "maturing out" of substance use and SUDs, given that substance use is incompatible with the demands of the roles of worker, spouse, and parent (Yamaguchi & Kandel, 1985). However, multiple factors may influence the maturing out of substance use. First, as described earlier, neurobiological research has documented a gradual maturation of cognitive control areas that continues into the early to mid-20s (Steinberg, 2008); these increases in cognitive control would be likely to reduce risk-taking behavior in general and substance use more specifically. Moreover, recent studies have demonstrated that age-related changes in personality—including declines in behavioral disinhibition/impulsivity and negative emotionality/neuroticism, and increases in conscientiousness—are correlated with declines in alcohol use in emerging adulthood (Littlefield, Sher, & Wood, 2009). There is also some recent evidence of a reverse direction of effect, such that alcohol use might influence age-related personality change, although the results are not totally consistent (Hicks, Durbin, Blonigen, Iacono, & McGue, 2012; Littlefield, Verges, Wood, & Sher, 2012).

Finally, there is substantial heterogeneity in age-related trajectories of substance use and SUDs. Several studies have suggested that an early age of substance use onset is one predictor of subsequent course and of clinical impairment. For example, Grant and Dawson (1997) found that alcohol use initiation before age 14 was associated with elevated risk for the development of alcohol use disorders. Similarly, Robins and Pryzbeck (1985) reported that early onset of illegal drug use (before age 15) was associated with increased likelihood of later drug use disorders. There is also heterogeneity in the speed of transition from initiation of use to

the development of clinical disorder. For example, adolescents whose parents have alcohol use disorders and those with externalizing symptoms move more quickly from onset to clinical disorders (Hussong, Bauer, & Chassin, 2008).

Researchers using mixture modeling have empirically identified multiple developmental trajectories of substance use within longitudinal studies. A particularly high-risk pattern combines early age of onset with a steeply escalating course of use. This has been found both for cigarette smoking (Chassin, Presson, Pitts, & Sherman, 2000) and for heavy drinking (Chassin, Pitts, & Prost, 2002; K. Hill, White, Chung, Hawkins, & Catalano, 2000). Moreover, studies of these early-escalating subgroups have shown them to be associated with a family history of use or disorder and high levels of conduct problems (Chassin et al., 2002; Costello et al., 1999; S. Y. Hill, Shen, Lowers, & Locke, 2000; Loeber, Stouthamer-Loeber, & White, 1999).

Conversely, longitudinal studies of adolescents have also identified a late-onset subgroup (at least late in the adolescent age period) whose smoking or heavy drinking does not begin until after the high school years (Chassin et al., 2002). For these adolescents, substance use initiation may be associated with decreases in parental supervision, perhaps during the transition out of the parental home. Adolescent substance use that begins after the high school years has been relatively neglected by researchers, and most prevention programs (with the exception of college student drinking initiatives) have been targeted at younger age groups. This represents an important area for future research.

RISK FACTORS AND ETIOLOGICAL MODELS

Risk factors for adolescent substance use and SUDs have been identified on multiple levels ranging from intrapersonal to macroenvironmental (see Hawkins et al., 1992), and have also been integrated into biopsychosocial theoretical models of etiology (see e.g., Sher, 1991). Given the heterogeneity of SUDs, it is unlikely that any one factor or etiological pathway could explain their development. For example, theory and research in alcoholism have suggested that subtypes of this disorder may have different etiological antecedents. In particular, researchers have distinguished between early-onset alcoholism (which has a higher prevalence in males, typically begins in adolescence, and is strongly associated with antisociality) and later-onset alcoholism (which is more strongly associated with neuroticism and negative affectivity; see, e.g., Cloninger, 1987).

Here we review some of the major risk factors and etiological models, with an emphasis on recent empirical evidence. These models suggest that the antecedents and etiological pathways into adolescent SUDs have their roots in earlier stages of development. In discussing the etiology of these SUDs, it is important to remember that they represent only a segment of a larger series of stages in substance use progression. These stages include initiation, experimental or occasional use, regular or escalating use, and problem use, as well as cycles of cessation and relapse (Flay, d'Avernas, Best, Kersell, & Ryan, 1983; Glantz & Pickens, 1992). As such, it is likely that movement through the different stages has different etiological determinants. However, existing empirical studies have often blurred these distinctions, and many of the existing data refer to predictors of adolescent substance use rather than clinical SUDs. Thus the existing database makes it difficult to specify etiological models of transition that are unique to different stages of substance use behavior.

Family History and Genetic Risk

A robust finding in the literature is that adults whose parents have a history of SUDs are at elevated risk for substance use and SUDs (McGue, 1994; Milne et al., 2009), although the magnitude of the risk varies substantially across samples. For example, parent alcoholism raises risk for offspring alcoholism anywhere from a risk ratio of 2–3 in community samples, to a risk ratio of 9 in severely alcohol-dependent and antisocial samples (McGue, 1994; Russell, 1990). There is also elevated risk (as high as eightfold) for SUDs among relatives of probands with SUDs (Merikangas et al., 1998).

Family history risk is also associated with adolescent substance use, including adolescent onset of substance use (Chassin et al., 2000; Costello et al., 1999), persistence of substance use over time (Chassin et al., 2000), and trajectories of heavy substance use and SUDs starting in adolescence (Chassin, Flora, & King, 2004; Jackson, Sher, & Wood, 2000). Studies suggest that this family history risk for substance use and SUDs in adolescence has both heritable and environmental mediators, and that the relative influence of each changes over the course of development. Adolescent substance use phenotypes are strongly influenced by common environmental factors. However, over the course of adolescence the influence of genetic factors on these

phenotypes tends to increase, while the influence of environmental factors tends to decrease (Dick, Pagan, et al., 2007; Kendler, Schmitt, Aggen, & Prescott, 2008; Rose, Dick, Viken, & Kaprio, 2001; Rose, Dick, Viken, Pulkkinen, & Kaprio, 2001).

These findings may in part be explained by the fact that adolescents are relatively less able than adults are to choose their social environments. This difference in autonomy may result in lowered opportunities for adolescents to express their genetic predispositions (Meyers & Dick, 2010). On the other hand, adults have greater control over their environments, and this "niche picking" may result in greater gene–environment covariation in adult social environments. Supporting this notion are findings reported by Dick, Pagan, and colleagues (2007) demonstrating that genetic influences on adolescent smoking decreased, and environmental influences increased, with higher levels of parental monitoring. Accordingly, these data suggest that the greater observed effects of the environment on adolescent substance use may result in part from the more restrictive environments of adolescents compared to adults. In addition, developmentally limited forms of adolescent substance use may mask genetic effects that become more prominent once these forms of use have remitted.

Studies have also revealed differences in the heritability of different developmental stages of substance use. For example, some research indicates that shared environmental influences play a more prominent role in substance use initiation, whereas genetic and unique environmental influences play a larger role on heavier/problematic use in both adolescents and adults (Fowler et al., 2007). However, other studies report a greater genetic influence on substance initiation compared to heavier/problematic use, conditional on the substance being investigated and on gender (McGue, Elkins, & Iacono, 2000; Rhee et al., 2003).

Another important consideration in the heritability of adolescent substance use comes from recent evidence indicating that this problem behavior is simply one way in which genetic risk for a spectrum of externalizing disorders is manifested. For example, a robust finding in the literature is that shared genetic factors account for the co-occurrence of childhood CD symptoms and both concurrent and later substance use (e.g., Hicks, Krueger, Iacono, McGue, & Patrick, 2004; Krueger et al., 2002; Slutske et al., 1998; Young, Stallings, Corley, Krauter, & Hewitt, 2000). In an adolescent sample, Young and colleagues (2000) found that CD, ADHD, substance experimentation, and novelty seeking were accounted for by a single, highly heritable, latent phenotype; Krueger and colleagues (2002) similarly found that a higher-order, highly heritable externalizing factor linked SUDs, antisocial behavior, and dishinhibited personality in 17-year-old twins. In addition, several candidate gene studies have found that adult substance use problems and adolescent behavioral problems may share genes (e.g., Dick et al., 2006; Dick, Agrawal, et al., 2007; Latendresse et al., 2011). Together, these findings suggest that the co-occurrence among externalizing disorders is in part accounted for by a common genetic vulnerability. Furthermore, researchers have posited that the underlying inherited phenotype that unifies the externalizing disorders is behavioral undercontrol/disinhibition (Zucker, Heitzeg, & Nigg, 2011).

The current literature emphasizes the importance of the environment's potential moderating effects in genetic studies of adolescent substance use. Although the literature with measured genes is just developing and there is concern about failures to replicate, several gene × environment interaction (G×E) studies have uncovered stronger genetic predispositions towards substance use in the context of higher-risk environments. Some of the environmental variables that have been shown to moderate genetic risk for adolescent substance use in this manner across both candidate gene and twin studies include parental monitoring (Dick et al., 2009; Dick, Pagan, et al., 2007; Latendresse et al., 2011), religiosity (Koopmans, Slutske, van Baal, & Boomsma, 1999), peer alcohol use (Dick, Pagan, et al., 2007), rural versus urban residency (Rose, Dick, Viken, & Kaprio, 2001), and parental rule setting (van der Zwaluw et al., 2010). Another framework within which to conceptualize G×E is the differential-susceptibility model, which posits that certain genes may render individuals more susceptible to the environment, regardless of whether the environment is positive or negative (Belsky et al., 2009). Thus individuals who possess "plasticity" genotypes would have the worst outcomes in the context of high-risk environments, but the best outcomes in the context of positive environments. For example, Laucht and colleagues (2012) found that adolescents homozygous for the Met allele of the COMT $Val^{158}Met$ polymorphism had higher levels of drinking under conditions of lower parental involvement and supervision, but also had reduced levels of drinking under conditions of higher parental involvement and supervision.

Research has also highlighted the importance of endophenotypes in genetic studies of adolescent sub-

stance use. "Endophenotypes" are measurable indices that are associated with a phenotype of interest, are heritable, may cosegregate with disease, and are often known or hypothesized to have a closer proximity to the biology underlying the disorder (Gottesman & Gould, 2003; Lynskey, Agrawal, & Heath, 2010). Identifying endophenotypes of SUDs and studying their genetic correlates will be advantageous because endophenotypes can lead to the identification of cases that are less likely to be etiologically heterogeneous than SUD status would be. Endophenotypes may aid in determining the mechanisms through which genes affect SUDs, and they may reduce the number of false positives and negatives in case status determination (Iacono, Carlson, & Malone, 2000). In adolescence, some endophenotypes of substance use have been proposed, including reduced P300 (Carlson, Iacono, & McGue, 2004), neurobehavioral disinhibition (Tarter, Kirisci, Habeych, Reynolds, & Vanyukov, 2004), subjective response to substances (e.g., Ehringer et al., 2007), and impulsivity (Esposito-Smythers, Spirito, Rizzo, McGeary, & Knopik, 2009). Although some work has linked genes to endophenotypes of adolescence substance use (e.g., Esposito-Smythers et al., 2009; Zeiger et al., 2008), more research is needed to identify other relevant endophenotypes in adolescence and the genetic correlates of these constructs.

Over the past several years, the literature on gene identification has grown rapidly. One difficulty associated with gene identification efforts in adolescents is categorizing those individuals who carry an unaffected status only because they have yet to manifest the disorder. This ambiguity can make it difficult to correctly identify those genomic regions that contribute to risk for substance use in adolescence. Although a review of this literature is beyond the scope of this chapter, several studies specifically examining the genetics of adolescent substance use include Stallings and colleagues (2003), Corley and colleagues (2008), and Zeiger and colleagues (2008). Reviews of the broader molecular genetics literature as it relates to substance use can be found in Foll, Gallo, Strat, Lu, and Gorwood (2009), Agrawal and Lynskey (2009), Dick and Foroud (2003), and Edenberg and Foroud (2006). Provided in this chapter are examples of some of the genomic regions that have been implicated in the etiology of adolescent substance use and SUDs through their influences on deviant peer affiliation and parenting behaviors, as well as their interactions with environmental variables.

Although studies indicate significant heritability for substance use and SUDs in adolescence, family history risk can also exert influence through fetal exposure mechanisms. For example, one study found that prenatal exposure to marijuana was associated with greater frequency of adolescent marijuana use, even after the researchers controlled for potential confounding variables such as adolescents' current substance use, pubertal stage, sexual activity, delinquency, peer drug use, family history of drug disorder, and home-environmental variables (Day, Goldschmidt, & Thomas, 2006). Similarly, Disney, Iacono, McGue, Tully, and Legrand (2008) found that prenatal exposure to alcohol raised risk for CD symptoms (a behavioral correlate of alcohol and drug use) in adolescents, even after the investigators controlled for parental SUDs, antisocial/behavioral disorders, and other potential confounding variables. On the other hand, using a more comprehensive measure of familial risk for alcohol problems that assessed both first- and second-degree relatives, S. Y. Hill, Lowers, Locke-Wellman, and Shen (2000) found no effect of prenatal alcohol and nicotine exposure on child/adolescent externalizing problems above and beyond this familial risk. Although conflicting data exist, a review of the literature by Glantz and Chambers (2006) concluded that prenatal exposure to illicit drugs increased risk for offspring SUDs beyond the risk contributed by parental SUDs, although the extent of this increased risk is unknown.

Given that a family history of SUDs is a well-established and robust risk factor for adolescent SUDs, an important goal for research is to understand how this risk is mediated. As described above, studies have demonstrated that there are both genetic and environmental components to the intergenerational transmission of risk. Risk may be mediated through personality and temperamental characteristics (e.g., propensities for negative affectivity, poor self-regulation, impulsivity, sensation seeking); through individual differences in the pharmacological effects and reinforcement value of substances; and through the effects of risky environments. Given the complexity of these processes, researchers have postulated multiple and interrelated pathways of risk that are biopsychosocial in nature. A heuristic model of such pathways has been offered by Sher (1991) and provides the guiding framework for the current review. Sher hypothesizes that vulnerability to SUDs can be described by three submodels or pathways: a deviance-proneness pathway, a pathway emphasizing stress and negative affect, and a pathway that focuses on substance use effects (the enhanced-reinforcement pathway). These pathways are not meant to be mutually exclusive; indeed, the same factors can

contribute to more than one pathway. Although Sher's model was proposed to explain the effects of familial alcoholism on vulnerability to alcoholism, the same pathways can be examined with respect to SUDs more broadly.

THE DEVIANCE-PRONENESS SUBMODEL

Sher's (1991) deviance-proneness submodel is depicted in Figure 4.1 (with the exception of contributions from negative affect, which are considered within the stress and negative affect submodel). In general, the deviance-proneness submodel suggests that the development of SUDs occurs within a broader context of the development of conduct problems and antisociality. Adolescents at risk for SUDs are thought to be temperamentally "difficult," with a heritable predisposition to behavioral undercontrol (Iacono, Malone, & McGue, 2008). They are also considered to be prone to cognitive deficits—including deficits in verbal skills and executive functioning (e.g., working memory, response inhibition, and attentional control)—that contribute to a lack of behavioral and emotional self-regulation. In addition, high-risk children are thought to receive poor parenting (and indeed to evoke poor parenting because behaviorally undercontrolled children are difficult to parent). This combination of temperamental, cognitive, and environmental risk factors sets the stage for failure at school and ejection from the mainstream peer group, which may result in affiliation with deviant peers who provide opportunities, models, and approval for alcohol and drug use. Because this submodel considers substance use within the broader context of antisocial behavior, it is quite similar to theories that attempt to explain the etiology of aggression and conduct problems more generally (see Kimonis, Frick, & McMahon, Chapter 3, this volume).

Temperament and Personality

Numerous studies report that temperamental and personality traits reflecting behavioral undercontrol and poor self-regulation are associated with adolescent substance use problems. For instance, in two reviews, the personality characteristics most consistently associated with adolescent substance use included unconventionality, low ego control, sensation seeking, aggression,

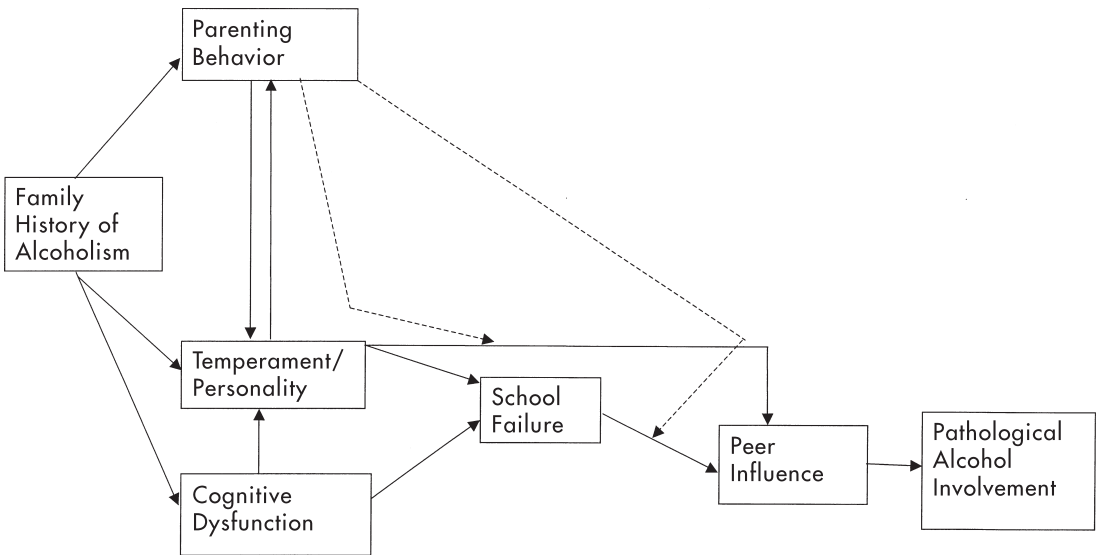

FIGURE 4.1. Schematic diagram of Sher's (1991) deviance proneness submodel. Mediating paths are indicated by solid lines; moderating paths are indicated by dashed lines. The effects of emotional distress (depicted in Sher's original 1991 model) are omitted here and depicted in the stress and negative affect submodel (Figure 4.2). From Sher (1991). Copyright 1991 by University of Chicago Press. Adapted by permission.

impulsivity, and an inability to delay gratification (Bates, 1993; Hawkins et al., 1992).

Longitudinal research has demonstrated that childhood temperamental characteristics reflecting undercontrolled behavior are longitudinally predictive of later substance use problems in adolescence and young adulthood. For instance, Block and colleagues (Block, Block, & Keyes, 1988; Shedler & Block, 1990) found that adolescents who used marijuana at least weekly were characterized as children by heightened levels of behavioral undercontrol and interpersonal alienation, and these traits were observable as early as 3–4 years of age. Similarly, Caspi, Moffitt, Newman, and Silva (1996) found that 3-year-old boys described by others as impulsive, restless, and distractible were at increased risk for an SUD diagnosis by age 21. Lerner and Vicary (1984) found that 5-year-old children with "difficult" temperamental profiles, including high levels of behavioral reactivity/emotionality and slow adaptability, were more likely to use substances in adolescence and young adulthood than children not characterized as "difficult" were. Brook, Whiteman, Cohen, Shapiro, and Balka (1995) found that childhood characteristics of unconventionality and poor control of emotions were associated with increased levels of drug use in adolescence and young adulthood. Such findings suggest that poor self-regulation and undercontrolled behavior are not simply correlates of problematic substance use, but prospectively predict future adolescent drug and alcohol problems, although causal mechanisms are not known.

As noted earlier, several biobehavioral markers of behavioral undercontrol, and consequent risk for adolescent substance use problems, have been identified. One is a diminished P3 component in event-related potentials (ERPs). P3 components of ERPs occur approximately 300 milliseconds after the presentation of a novel or task-relevant stimulus. Reductions in P3 amplitude have been reported for several forms of undercontrolled behaviors, including antisocial personality disorder, ADHD, and aggression, as well as SUDs (Begleiter & Porjesz, 1999; Iacono, Carlson, Taylor, Elkins, & McGue, 1999; Klorman, 1992). Moreover, young children of parents with alcohol use disorders also show reduced P3 amplitude even before the onset of drinking (Begleiter & Porjesz, 1999), and reduced P3 amplitude predicts drinking onset in this population (S. Y. Hill, Shen, et al., 2000; Iacono et al., 1999). Given these data, reductions in P3 amplitude have been viewed as a potential marker for behavioral undercontrol as a diathesis for early-onset substance use. Other candidate biobehavioral markers for behavioral undercontrol and risk for substance use include neurochemical and neuroendocrine responses, as well as ability to modulate autonomic nervous system reactivity (Iacono et al., 1999; see Tarter et al., 1999, for a review).

Additional data suggest that the intergenerational transmission of adolescent substance use problems may be mediated by a predisposition toward behavioral undercontrol. For instance, research has consistently found that children of parents with alcohol use disorders (a population at heightened risk for the development of alcohol problems) show high levels of impulsivity, aggression, and high levels of motor activity (e.g., Blackson, 1994; Jansen, Fitzgerald, Ham, & Zucker, 1995; Martin et al., 1994; Tarter, Alterman, & Edwards, 1985); these traits are observed in their alcoholic parents as well (e.g., Blackson, 1994). Data from twin studies further suggest that indicators of behavioral undercontrol have substantial heritability, and may serve to increase risk for substance use problems in adolescents, particularly in the context of familial alcoholism. Ongoing longitudinal data from the Minnesota Family Twin Study (Iacono et al., 1999) have shown substantial heritability for various indices of undercontrol, including reduced constraint, poor psychophysiological modulation in response to stress, and high levels of externalizing behavior. These traits were also more likely to characterize children with a family history of alcoholism. Specifically, sons of "undersocialized alcoholics" (i.e., parents with alcohol use disorders and comorbid externalizing disorders) were more likely than sons of "socialized alcoholics" (i.e., parents with alcohol use disorders but without comorbid externalizing disorders) or sons of nonalcoholic parents to meet diagnostic criteria for ADHD, CD, or antisocial behavior; to have had contact with the police; and to have a personality style typified by low constraint. In turn, these risk factors were strongly associated with a diagnosis of adolescent SUDs, even after the researchers controlled for effects of paternal alcoholism. Taken together, these findings support a genetic diathesis model for adolescent substance use problems, with the diathesis consisting of heritable individual differences in behavioral undercontrol.

However, although behavioral undercontrol is a well-recognized risk factor for adolescent substance use, it is important to note that behavioral undercontrol is a complex and heterogeneous construct. For example, from a personality perspective, the "propensity to rash action" has been proposed to comprise five dis-

tinct dimensions, including sensation seeking, lack of perseverance, lack of premeditation (acting without planning), and positive and negative urgency (Birkley & Smith, 2011; Lynam, 2011). In general, it has been suggested that three types of processes—those involving reward sensitivity and the seeking of reward; harm avoidance and the avoidance of punishment; and inhibitory control and the ability to restrain behavior to avoid negative consequences—are particularly important for substance use and SUDs (Castellanos-Ryan, Rubia, & Conrod, 2011; Goldstein & Volkow, 2002). Thus adolescents who show elevated levels of sensation seeking and reward seeking, those who show low levels of harm avoidance, and those with low levels of inhibitory control are at risk for substance use. Moreover, dual-process models (e.g., Wiers, Ames, Hofman, Krank, & Stacy, 2010) propose that substance use behavior is the result of an interaction between automatic associations that promote approach or avoidance of substances and inhibitory control. Thus, for example, positive automatic associations with substance use behavior will be more likely to drive behavior in circumstances when more effortful, reflective, top-down cognitive control is weakened. Because cognitive control is likely to be weakened in contexts of high emotional arousal, highly arousing peer social contexts may create a particularly high risk for adolescent substance use.

Although temperament is presumed to reflect a relatively stable behavioral style, the effects of temperament on developmental outcomes are also presumed to be modified by the environment, particularly by parenting and family environments. In studies of adolescent externalizing behavior, it has been reported that poor parenting is particularly detrimental when adolescents show high levels of temperamental reactivity or deficient regulation (e.g., Bates, Pettit, Dodge, & Ridge, 1998; Stice & Gonzales, 1998). Similar results have been reported with respect to adolescent substance use. Specifically, Wills, Sandy, Yaeger, and Shinar (2001) examined moderating effects of temperament and parenting on adolescent substance use (including alcohol, tobacco, and marijuana use), and found that parental risk factors (i.e., substance use, conflict) differentially exacerbated risk for substance use among adolescents with high activity levels and high levels of negative emotionality. Such findings suggest that despite their heritable bases, the effects of temperamental characteristics on substance use outcomes may be either exacerbated or buffered by the type of parenting that adolescents receive. However, studies have also found that the protective effects of parenting and family environment on substance use outcomes are reduced at higher levels of behavioral undercontrol and familial alcoholism, and are absent at the highest levels of risk (King & Chassin, 2004; Zhou, King & Chassin, 2006).

Cognitive Functioning

Additional evidence for deficient self-regulation as a risk factor for adolescent substance use and SUDs may be found at the level of cognitive functioning, in the form of deficits in executive functioning. "Executive functioning" is a multidimensional construct that encompasses a variety of related higher-order cognitive processes allowing for future-goal-oriented behavior. A myriad of different processes have been included in this construct, including planning, organizational skills, selective attention, hypothesis generation, cognitive flexibility, working memory, maintenance of cognitive set, decision making, judgment, inhibitory control, and self-regulation (Lezak, Howieson, Bigler, & Tranel, 2012; Spreen & Strauss, 1998).

From the point of view of risk for adolescent SUDs, a common theme is that deficits in executive functioning make it difficult for children both to create strategic and goal-oriented responses to environmental stimuli, and to use feedback to modify behavior in response to environmental events (Peterson & Pihl, 1990). Such cognitive difficulties in creating goal-directed responses to environmental stimuli then produce heightened levels of behavioral undercontrol, such as impulsive and externalizing behavior, which raise risk for substance use and SUDs (Peterson & Pihl, 1990).

Adolescents with SUDs have shown deficits in cognitive functioning. For example, Brown and colleagues reported that relative to youth without alcohol problems, alcohol-dependent adolescents were characterized by poorer retention of verbal and nonverbal information, poorer attentional capacities, and deficits in visual–spatial planning (Brown, Tapert, Granholm, & Delis, 2000; Tapert & Brown, 1999). Moreover, substance-dependent adolescents with poor cognitive skills and poor coping skills were also more likely to continue using alcohol and drugs over time (Tapert, Brown, Myers, & Granholm, 1999). Similarly, Giancola, Mezzich, and Tarter (1998) found that adolescent girls with SUDs exhibited poorer executive functioning than that of controls.

Deficits in executive functioning have also been found to be associated with alcohol use in communi-

ty samples in late adolescence. For example, Deckel, Bauer, and Hesselbrock (1995) found that lower levels of executive functioning were associated with earlier drinking onset, greater frequency of drinking to get drunk, and higher scores on the Michigan Alcoholism Screening Test in a sample of young adults. Research with college students has yielded similar findings. Giancola, Zeichner, Yarnell, and Dickson (1996) found that lower levels of executive functioning were associated with more adverse consequences of drinking, even after the investigators controlled for absolute levels of alcohol consumption. Sher, Martin, Wood, and Rutledge (1997) found that first-year undergraduates with diagnoses of alcohol use disorders performed more poorly than did students without such diagnoses on measures of visual–spatial ability, motor skill, and attention. However, these studies were cross-sectional in design, and thus could not speak to the directionality of effects.

Several studies have also suggested that executive functioning deficits are found in children of parents with alcohol use disorders—even at early ages, before alcohol problems have developed (e.g., Corral, Holguin, & Cadaveira, 1999; Drejer, Theilgard, Teasdale, Schulsinger, & Goodwin, 1985; Giancola, Martin, Tarter, Pelham, & Moss, 1996; Harden & Pihl, 1995; Peterson, Finn, & Pihl, 1992; Poon, Ellis, Fitzgerald, & Zucker, 2000). These data suggest that executive functioning may be an antecedent risk factor rather than a result of alcohol consumption in this population. Similarly, Deckel and Hesselbrock (1996) found that children of alcoholic parents with poorer executive functioning showed greater increases in alcohol consumption over a 3-year period than did children of alcoholic parents with higher levels of executive functioning, suggesting that executive functioning might be a prospective predictor of substance use among high-risk adolescents. In a separate longitudinal investigation, Atyaclar, Tarter, Kirisci, and Lu (1999) reported significant independent effects of paternal substance abuse and executive functioning on several measures of adolescent drug use, including the lifetime number of drugs used, lifetime exposure to cannabis and tobacco, and severity of consequences resulting from drug use.

Although these findings suggest that executive functioning impairments play an important role in the pathogenesis of substance use, particularly among those at high risk because of parental alcoholism, it is important to note that these studies have not been consistently replicated. Many investigators have not found differences in cognitive functioning between children of alcoholic parents and controls (e.g., Bates & Pandina, 1992; Wiers, Gunning, & Sergeant, 1998). Moreover, measures of attention and working memory have not consistently been found to predict adolescent substance use (Castellanos-Ryan et al., 2011; Handley et al., 2011), and at least one review of the literature has concluded that evidence for executive functioning deficits in children of alcoholic parents is weak and inconsistent across studies (Hesselbrock, Bauer, Hesselbrock, & Gillen, 1991). Response inhibition has been found to have a unique effect on alcohol-related problems and illegal drug use, over and above externalizing symptoms (Nigg et al., 2006), but other studies have not found a relation between response inhibition and cannabis use (Griffith-Lendering, Huijbregts, Vollebergh, & Swaab, 2012) or found that response inhibition predicted conduct problems but not substance use (Castellanos-Ryan et al., 2011; Handley et al., 2011). Given the lack of consistent effects of executive functioning on adolescent substance use, one possibility is that executive functioning is better conceptualized as a moderator of more automatic processes (as proposed by dual-process models; Wiers et al., 2010) than as a main-effect predictor. Alternatively, it has been argued that inconsistent findings for executive functioning measures may be due to problems with the measures themselves, including problems of reliability and weak ecological validity (Barkley, 2012).

Finally, adolescent substance use is related to performance on task measures of risk taking and affective decision making, such as the Balloon Analogue Risk Task (BART; Lejuez et al., 2002) and the Iowa Gambling Task (IGT; Bechara, Damasio, Damasio, & Anderson, 1994), as well as delay discounting. Greater delay discounting of reward (Reynolds & Fields, 2012), poorer performance on the IGT (Goudriaan, Grekin, & Sher, 2007; Xiao et al., 2013), and greater risk taking on the BART (Aklin, Lejuez, Zvolensky, Kahler, & Gwadz, 2005; Lejuez et al., 2002) are associated with more adolescent substance use. However, these are complex tasks for which performance is determined by multiple processes. Thus the mechanisms that link performance on these tasks to adolescent substance use are not always clear.

Parenting and Socialization

Parenting that combines high levels of nurturance with consistent discipline—in other words, what Baumrind

(1991) has termed "authoritative" parenting—has been associated with a lowered risk of adolescent substance use (Adalbjarnardottir & Hafsteinsson, 2001; Hawkins et al., 1992). For example, low levels of parental social support and discipline prospectively predict increases in adolescent substance use over time (King & Chassin, 2004; Stice & Barrera, 1995; Wills, Resko, Ainette, & Mendoza, 2004). In addition, higher levels of harsh parenting (Brody & Ge, 2001) and family conflict have been found to be associated with higher levels of adolescent substance use and SUDs, at least in African American youth. This relation may also be stronger for females than males and for those with elevated negative emotionality (Skeer et al., 2011; Skeer, McCormick, Normand, Bika, & Gilman, 2009; Webb & Baer, 1995; Wills, Sandy, Yaeger, & Shinar, 2001).

Low levels of parental monitoring/knowledge have also been shown to prospectively predict both the onset of substance use and heavy drinking in adolescence, although this effect may differ for males and females (Barnes, Hoffman, Welte, Farrell, & Dintcheff, 2006; Borawaski, Ievers-Landis, Lovegreen, & Trapl, 2003; Coley, Votruba-Drzal, & Schindler, 2008; Dishion, Nelson, & Kavanagh, 2003; King & Chassin, 2004; Reifman, Barnes, Dintcheff, Farrell, & Uhteg, 1998; Steinberg, Fletcher, & Darling, 1994). However, research concerning parent monitoring suggests that, for the most part, parents obtain information about their adolescents because the children choose to disclose information, rather than because parents ask their children about their lives (Fletcher, Steinberg, & Williams-Wheeler, 2004; Laird, Pettit, Bates, & Dodge, 2003; Stattin & Kerr, 2000). Therefore, findings supporting a link between parental monitoring/knowledge and adolescent substance use may really reflect the fact that adolescents who use substances tell their parents less about their lives. Research examining the ease with which adolescents talk to their parents suggests that among sons, communication with fathers is protective against marijuana use and cigarette smoking (Luk, Farhat, Iannotti, & Simons-Morton, 2010).

Finally, parental divorce and living in single-parent families (Duncan, Duncan & Hops, 1996; Waldron, Bucholz, Madden, & Heath, 2009) have been associated with higher levels of adolescent substance use, although some have found that this effect only holds for those not associating with deviant peers (Eitle, 2005). It is also unclear whether single-parent family structure or correlated processes (such as increased conflict or disrupted parent–adolescent relationships) more strongly predict substance use (Brody & Forehand, 1993).

Not only is adolescent substance use related to general parenting style, family climate, and parent–adolescent relationships, but data also suggest that adolescent substance use may be related to parents' specific socialization about the use of substances. That is, parents set not only general rules and expectations for adolescent behavior, but also rules and policies about the use of tobacco, alcohol, and other drugs. They may discuss reasons not to use these substances, and may punish substance use behavior. Cross-sectional and longitudinal studies have suggested that these forms of socialization that are specific to substance use may deter adolescents' substance use behavior (Chassin et al., 2005; Chassin, Presson, Todd, Rose, & Sherman, 1998; de Leeuw, Scholte, Harakeh, Leeuwe, & Engels, 2008; Jackson & Henriksen, 1997).

Thus available data suggest that parent socialization—either in the form of general parenting and parent–adolescent relationships, or in the form of specific attempts to deter substance use—may influence the development of adolescent substance use behavior. Moreover, although data are not extensive, several mediational models suggest that the effects of parenting on adolescent substance use may be mediated through the effects of parenting on affiliations with deviant peers, as specified in various versions of the deviance-proneness pathway (Chassin, Curran, Hussong, & Colder, 1996; Dishion, Capaldi, Spracklen, & Li, 1995; Dishion, Patterson, & Reid, 1988; Roberts et al., 2012).

Recent work on the effects of parenting on adolescent substance use has examined whether these effects are unique, over and above gene–environment covariation (in this case, the relation between genetic risk and parenting). There is likely to be both evocative gene–environment covariation (such that adolescents at genetic risk evoke particular parenting) and passive gene–environment covariation (such that parents pass on a genetic predisposition to substance use) (Reiss, Neiderhiser, Hetherington, & Plomin, 2000). Studying the effects of parenting on adolescent substance use without considering correlated genetic risk is potentially misleading because parenting may be simply a marker of genetic risk or may be a mediator of genetic effects on substance use. Twin studies have found that genetic factors play a significant role in predicting parental affection, conflict, control, and knowledge of children's activities (Cleveland & Crosnoe, 2004; Plomin, Reiss, Hetherington, & Howe, 1994; Reiss et al.,

2000), suggesting the importance of gene–environment covariation.

Recent work has begun examining the link between specific genes and parenting behaviors, with the serotonin transporter polymorphism (5-HTTLPR), the oxytocin receptor gene (OXTR), and the dopamine D2 receptor gene (DRD2) receiving some support for their links to anxiety and mood, which are implicated in parental sensitivity, engagement, and secure parent–child attachment (Bakermans-Kranenburg & van IJzendoorn, 2006; Gillath, Shaver, Baek, & Chun, 2008; Laucht et al., 2012). In addition to research focusing on genes that might predict how caregivers parent their children, there is also work implicating particular receptor systems in child behaviors that evoke certain responses from parents. For example, because of their link to reward, other genes from the dopamine, gamma-aminobutyric acid (GABA), and opioid systems may affect adolescents' risk-taking behavior and likelihood of associating with deviant peers, which may in turn affect the parenting that they receive (Edenberg & Foroud, 2006; Foley et al., 2004; Fowler, Settle, & Christakis, 2011; Rowe et al., 2001; Vaughn, Beaver, DeLisi, Perron, & Schelbe, 2009).

As discussed earlier, there is also work suggesting that genes and parenting interact to predict adolescent substance use outcomes. Although, as noted earlier, there is a need for replication, some data suggest that genes are more predictive of substance use and related outcomes at higher levels of environmental risk (e.g., lower levels of parental monitoring/knowledge; Dick et al., 2009; Dick, Pagan, et al., 2007). Others have found that individuals at higher risk on "plasticity genes" are more vulnerable to both positive and negative environments (Bakermans-Kranenburg & van IJzendoorn, 2006; Belsky & Pluess, 2009).

Finally, less is known about how parenting and family environment factors might differentially affect adolescent SUDs across different ethnic or cultural groups. Although there is evidence for generalizability of familial influences across ethnic groups (Barrera et al., 1999; Nowlin & Colder, 2007), other studies have reported differential magnitudes of relations between parenting and substance use across ethnicity (e.g., Bohnert, Rios-Bedoya, & Breslau, 2009, and Griesler & Kandel, 1998, for tobacco use), or have suggested that the relations between authoritative parenting and adolescent deviance-proneness may vary as a function of ethnicity and community context (Lamborn, Dornbusch, & Steinberg, 1996).

School Failure and Academic Aspirations

Children who are temperamentally poorly regulated, who receive poor parental nurturance and involvement and deficient parental monitoring and discipline, who have parents with less education, and who have cognitive deficits in executive and verbal functioning are at heightened risk for school failure (Blair & Diamond, 2008; Bryant & Zimmerman, 2002; Patterson, 1986; Valiente et al., 2011). Moreover, school failure itself may further elevate risk for the onset of adolescent substance use through several mechanisms. First, school failure is a source of stress and negative affect, which can raise risk for substance use to regulate that affect. Second, school failure can weaken school attachment (e.g., aspirations for higher education, values placed on academic success, participation in mainstream school activities). Many theories of adolescent substance use and deviant behavior—including social control theory (Elliott, Huizinga, & Ageton, 1985), the social development model (Catalano, Kosterman, Hawkins, Newcomb, & Abbott, 1996), and problem behavior theory (Jessor & Jessor, 1977)—suggest that estrangement from mainstream social institutions makes adolescents more vulnerable to engaging in problem behaviors (including substance use) because they feel less bound by conventional social norms and values. Moreover, adolescents who are not committed to academic success will experience less role conflict between the demands of academic roles and the impairment produced by alcohol and drug use, so that they have less reason to refrain from substance use. Third, school failure can increase risk for adolescent drug use because it raises risk for adolescents' ejection from a mainstream peer group, particularly if the school failure is associated with aggressive or underregulated behavior (Bryant, Schulenberg, O'Malley, Bachman, & Johnston, 2003; Dishion, Patterson, Stoolmiller, & Skinner, 1991; Flicek, 1992). Adolescents who are ejected from a mainstream peer group are more likely to affiliate with deviant peers, who model and approve of substance use behavior. Consistent with these mechanisms, available empirical evidence suggests that adolescents with poor grades (Bachman, Staff, O'Malley, Schulenberg, & Freedman-Doan, 2011; Crosnoe, 2006; S. C. Duncan, Duncan, Biglan, & Ary, 1998; Ellickson, Tucker, & Klein, 2008; Gau et al., 2007; Kandel, 1978; Luthar & D'Avanzo, 1999), those with low educational aspirations (Bachman et al., 2011; Paulson, Combs, & Richardson, 1990), those who are unhappy with school

(Fitzpatrick, Piko, Wright, & LaGory, 2005), and those who have low value and expectations for attaining educational success (Bergen, Martin, Roeger, & Allison, 2005; Jessor & Jessor, 1977; Luthar & Ansary, 2005) are more likely to use alcohol or drugs. However, it is important to note a potential exception to this pattern: Extremely high levels of pressure for academic success have been suggested to serve as a risk factor for substance use among affluent adolescents (Luthar & Latendresse, 2005).

Peer Influences

There is a strong relation between an adolescent's substance use and the substance use of the adolescent's friends (Bullers, Cooper, & Russell, 2001; Hawkins et al., 1992; Kandel, 1978; Rosenquist, Murabito, Fowler, & Christakis, 2010). Affiliation with a drug-using peer group elevates risk for adolescent substance use by providing models and opportunities for engaging in, as well as norms for, drug use (Oetting & Donnermeyer, 1998). When adolescents are in the presence of their peers, they take significantly more risks, suggesting that the presence of peers is particularly rewarding (Steinberg, 2008). Indeed, Chein and colleagues (2011) found that situations in which peers were present activated adolescent brain regions associated with reward.

Siblings are an additional source of peer influence on adolescent drug use (Conger & Rueter, 1996; Duncan, Duncan, & Hops, 1996; McGue, Sharma & Benson, 1996). For example, older siblings' drug use during adolescence and early adulthood has been found to prospectively predict younger siblings' use (Bricker, Peterson, Sarason, Andersen, & Rajan, 2007; van der Vorst, Engels, Meeus, Dekovic, & Leeuwe, 2007). However, the strength of the older siblings' influence is moderated by sibling relationship quality, such that a warm and supportive relationship with a delinquent older sibling represents high risk for substance use for the younger sibling (East & Khoo, 2005; Slomkowski, Rende, Conger, Simons, & Conger, 2001; Slomkowski, Rende, Novak, Lloyd-Richardson, & Niaura, 2005). In addition, the transmission of substance use from an older to a younger sibling occurs more often when the two are the same gender and close in age (Trim, Leuthe, & Chassin, 2005).

Even though peer use has been regarded as the strongest predictor of adolescent substance use, researchers have also questioned the interpretation of this relation. Because most studies ask adolescents to report on both their own use and the behavior of their friends, the magnitude of the correlation between peer use and adolescent use is inflated because adolescents who themselves use drugs overestimate their friends' use (Bauman & Ennett, 1996). Correlations between adolescents' and friends' drug use are lower—although still significant—when peers are surveyed directly (Kandel, 1978).

Although there are consistent relations between adolescent substance use and peer substance use in adolescence, these correlations are likely to result from two different processes: peer selection and influence. Individuals who use alcohol are likely to select similar alcohol-using friends (i.e., peer selection), and individuals whose friends either use alcohol or approve of alcohol use are likely to increase their alcohol use (i.e., peer influence). Numerous studies have tested whether selection or influence is driving the relation between an individual's substance use and that of his or her friends (Bauman & Ennett, 1996; Dishion & Owen, 2002; Simons-Morton & Farhat, 2010), with longitudinal studies reporting both peer selection and peer influence effects (Bullers et al., 2001; Dishion & Owen, 2002; Rosenquist et al., 2010).

However, some have found that peer selection effects are stronger than are influence effects (Bullers et al., 2001; Simons-Morton & Farhat, 2010). This has led researchers to speculate about the possibility of an active gene–environment correlation, such that adolescents with a particular genotype seek similar friends or friends who encourage substance use (Loehlin, 2010; Reiss et al., 2000). Indeed, genetic influences on affiliations with deviant or substance-using peers have been found both in twin studies (Cleveland, Wiebe, & Rowe, 2005; Fowler et al., 2007; Kendler & Baker, 2007) and with measured genes (Beaver, Wright, & DeLisi, 2008; Fowler et al., 2011; Vaughn et al., 2009). It is also possible that peer influences mediate the effects of genetic risk on substance use. That is, individuals of particular genotypes select substance-using friends, and those friends in turn influence them to use substances (Reiss et al., 2000). For example, Chassin and colleagues (2012) found that, for males, mu-opioid receptor (OPRM1) genetic variation predicted affiliations with alcohol-use-promoting peers, who increased risk for alcohol-related problems.

In addition to mediating genetic risk, it is possible that peer influences moderate genetic risk. Guo, Elder, and Hamilton (2009) found that the effects of genetic risk on adolescent drinking were larger for those with

heavier-drinking peers. Similarly, Agrawal and colleagues (2010) found that regular substance use was more heritable for women who reported more peer substance use. Peer environments that support alcohol use may act to expose genetic vulnerability and thus show larger genetic effects on drinking, whereas peer environments that constrain drinking may suppress effects of genetic risk. This G×E pattern may also vary with age. Kendler, Gardner, and Dick (2011) found that the interaction between peer group deviance and genetic risk on drinking was strong in early adolescence, weaker in middle adolescence, and nonsignificant in early adulthood. Finally, few G×E studies have been conducted with measured genes and peer influences. van der Zwaluw, Larsen, and Engels (2012) found no significant interactions between best friends' drinking and the dopamine D4 receptor (DRD4) in predicting adolescent drinking, but Johnson and colleagues (2010) found a significant interaction between peer influence and CHRNA5 in predicting problems with nicotine.

Childhood Conduct Problems

A central assumption of the deviance proneness model is that adolescent substance use disorders are related to the broader development of conduct problems and antisociality, and this assumption has widespread empirical support (Hawkins et al., 1992). Conduct problems and aggression predict adolescent substance use (Henry et al., 1993; Kellam, Brown, Rubin, & Ensminger, 1983), escalations in use over time (K. Hill et al., 2000; Hussong, Curran, & Chassin, 1998) and later SUD diagnoses (Chassin, Pitts, & DeLucia, 1999). Moreover, CD is a strong risk factor for adolescent SUDs (Clark, Parker, & Lynch, 1999; Costello et al., 1999; Disney, Elkins, McGue, & Iacono, 1999; Weinberg & Glantz, 1999), and conduct problems have been found to predict SUDs for both boys and girls (Chassin, Pitts, Delucia, & Todd, 1999; Costello et al, 1999; Disney et al., 1999). Interestingly, the relation has been somewhat specific to conduct problems, rather than including all externalizing disorders in general. For example, although ADHD is associated with SUDs, these associations seem largely mediated by the development of associated CD rather than specific to ADHD per se (Costello et al., 1999; Disney et al., 1999; Lynsky & Fergusson, 1995; Molina, Smith, & Pelham, 1999). An exception to this pattern occurs for tobacco problems, which have been linked to attention deficits even in the absence of CD (Disney et al., 1999; Elkins et al., 2007; McMahon, 1999).

THE STRESS AND NEGATIVE AFFECT SUBMODEL

Stress and negative affect mechanisms can be used to hypothesize that individuals who use substances in order to regulate or cope with stress and negative affect are at high risk for SUDs. Accordingly, children and adolescents who experience a high level of environmental stress and/or are temperamentally prone to experience negative affect may be at risk for substance use and SUDs to the extent that they use alcohol or drugs as a way to decrease this negative affect (i.e., as a form of self-medication). Sher's (1991) elaboration of this submodel is depicted in Figure 4.2. Although this submodel is intuitively appealing, it has not enjoyed consistent empirical support and remains less well established in the adolescent literature than the deviance-proneness submodel.

Numerous studies have shown that high levels of negative affect and internalizing symptoms commonly co-occur with adolescent substance use outcomes, including alcohol use, heavy drinking, alcohol use disorder, smoking, tobacco use disorder, cannabis use, nonmedical use of prescription drugs, and other illicit drug use (Deykin, Buka, & Zeena; 1992; Hussong, Jones, Stein, Baucom, & Boeding, 2011; Kassel, Stroud, & Paronis, 2003; Patton et al., 2002; Rohde, Lewinsohn, & Seeley, 1996; Waller et al., 2006; Wu, Ringwalt, Mannelli, & Paktar, 2008). In addition, multiple studies have provided strong evidence that adolescents who experience high levels of environmental stress are more likely to use substances (including alcohol, tobacco, and other drugs), and to escalate the quantity and frequency of their use over time (Chassin et al., 1996; Dube et al., 2006; Hoffman, Cerborne, & Su, 2000; Hussong & Chassin, 2004; Wills, Sandy, & Yaeger, 2002). Moreover, children and adolescents who are exposed to traumatic events, particularly childhood maltreatment (sexual, physical, or emotional abuse and emotional or physical neglect), may also be at risk for substance use problems. These include early onset of substance use (Keyes, Hatzenbuehler, & Hasin, 2011; Whitesell, Beals, Mitchell, Manson, & Turner, 2009), binge drinking (Cisler et al., 2011), alcohol-related problems (Sartor, Agrawal, McCutcheon, Duncan, & Lynskey, 2008), cannabis disorder symptoms (Rogosch, Oshri, & Cicchetti, 2010), and SUDs (Whitesell et al., 2009). Finally, support for a link between adolescent stress/negative affect and substance use is also provided by studies of adolescents in treatment for SUDs, which show that stress, negative affect, and depression are

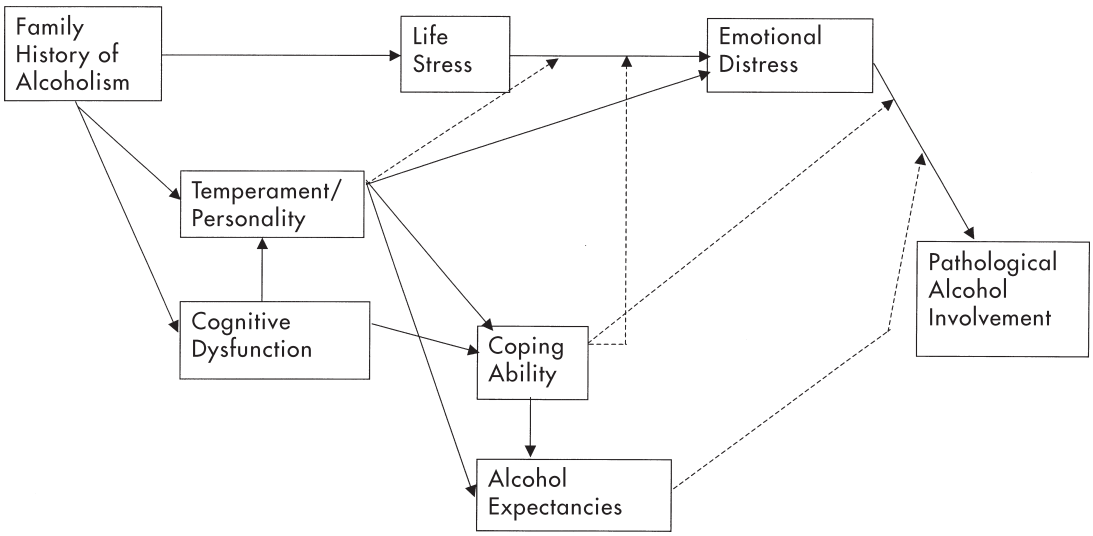

FIGURE 4.2. Schematic diagram of Sher's (1991) stress and negative affect submodel. Mediating paths are indicated by solid lines; moderating paths are indicated by dashed lines. From Sher (1991). Copyright 1991 by University of Chicago Press. Adapted by permission.

associated with relapse after treatment (Cornelius et al., 2003; McCarthy, Tomlinson, Anderson, Marlatt, & Brown, 2005; White et al., 2004).

Although it is clear that stress and negative affect are associated with adolescent substance use involvement, it is less clear whether negative affect and internalizing symptomatology are causes or consequences (or both) of adolescent substance use. Although several prospective studies have linked childhood and adolescent internalizing symptoms to future substance use initiation (King et al., 2004), increases in substance use over time (Mason, Hitchings, & Spoth, 2009), substance-related problems (Mason, Hitchings, & Spoth, 2007), and SUDs (Sung et al., 2004; Wittchen et al., 2007), effects are typically small and are only found for certain subgroups of individuals or at certain developmental periods. Moreover, many other prospective studies have failed altogether to find a significant internalizing pathway to substance use and SUDs during adolescence and early adulthood (Chassin, Pitts, DeLucia, & Todd, 1999; Hansell & White, 1991; K. Hill et al., 2000; Hussong et al., 1998).

One reason for these mixed findings is that adolescent internalizing symptoms often co-occur with externalizing symptoms (e.g., Lewinsohn, Shankman, Gau, & Klein, 2004), which have much stronger and more consistent effects on substance use outcomes (Dierker, Vesel, Sledjeski, Costello, & Perrine, 2007; Hallfors, Waller, Bauer, Ford, & Halpern, 2005; Hussong et al., 1998; King et al., 2004; Ohannessian & Hesselbrock, 2008). Although internalizing and externalizing mechanisms may each contribute unique risk for substance use outcomes, they may also interact with each other over development (Hussong et al., 2011). Unfortunately, the high rates of comorbidity among internalizing and externalizing symptoms during adolescence make it difficult to disentangle these effects (Hussong et al., 2011). Nonetheless, adolescents who display high levels of both internalizing and externalizing symptoms are likely to be at particularly high risk for substance use problems (Pardini, White, & Stouthamer-Loeber, 2007).

Another explanation for the inconsistent empirical support for stress and internalizing symptomatology as prospective predictors of substance use outcomes is that studies often use inappropriate time lags between assessments. Because self-medication is likely to involve using substances close to the time of experiencing a negative event (Park, Armeli, & Tennen, 2004), studies that examine associations between stress/negative affect and substance use over long periods of time may present a poor match between method and theory. Daily

diary and experience-sampling methods (e.g., Hussong, Hicks, Levy, & Curran, 2001) may be better suited for testing self-medication models of substance use. Conversely, others have argued that the time lag between assessments may not be long *enough*, given that an internalizing pathway to SUDs is typically characterized by late-onset substance use problems. Although research on the development of alcohol use disorders typically targets adolescents and young adults, negative affect alcoholism subtypes, such as Cloninger's (1987) Type 1 alcoholism and Zucker's (2006) negative affect alcoholism, posit *adult* rather than adolescent onset.

Among adolescents, however, direct and prospective internalizing effects may only be found for a small subgroup who have both early-onset and clinically significant internalizing symptomatology. Sihvola and colleagues (2008) found that early-onset (i.e., age 14) depression significantly predicted numerous substance use outcomes 3.5 years later, including daily smoking, illicit drug use, and frequency of alcohol use, even after the researchers controlled for comorbid disorders and baseline use. Yet, for most adolescents, early internalizing symptoms will *not* progress to substance use problems; whether negative affect/internalizing symptoms predict problematic substance use outcomes will depend on the extent to which these symptoms cause impairment in other, more proximal domains, such as involvement with deviant peers, social incompetence/rejection, and academic failure (Hussong et al., 2011; Zucker, 2008). In other words, the effects of stress and negative affectivity on substance use during adolescence may be better characterized as indirect than as direct.

The associations between adolescent negative affect/internalizing symptoms and substance use also appear to vary according to the specific type of affect (for a review, see Colder, Chassin, Lee, & Villalta, 2009). As a result, studies that aggregate different types of affect (e.g., depression, anger, anxiety) and internalizing symptoms may obscure their relations with substance use. With respect to depression, research indicates that adolescent depression and substance use may interact with each other to reciprocally influence the severity and course of each problem (Colder et al., 2009). Depressed adolescents may find that experimenting with substances temporarily relieves their mood, reinforcing additional substance use and resulting in the development of SUDs; conversely, repeated substance use may lead to biochemical changes that induce additional depressive episodes (Rao, 2006). Although anger is cross-sectionally related to substance use, it has failed to prospectively predict substance use outcomes (e.g., Swaim, Deffenbacher, & Wayman, 2004; Weiner, Pentz, Turner, & Dwyer, 2001). Affect regulation models of substance use also posit a motivation to use substances in order to increase positive affect (Cooper, Frone, Russell, & Mudar, 1995). Among the few studies that have examined positive affect separately from negative affect, low positive affect has been linked with substance use and substance use escalation (Wills, Sandy, Shinar, & Yaeger, 1999), as well as with adolescent substance use problems among adolescents with high levels of impulsivity (Colder & Chassin, 1997). However, other studies find that positive affect and adolescent substance use are unrelated (Hussong & Hicks, 2003).

The link between anxiety and substance use vulnerability appears to depend on the type of anxiety symptoms. For instance, late childhood separation anxiety may actually reduce the likelihood of substance use during adolescence (Kaplow et al., 2001), whereas adolescent symptoms of generalized anxiety have been linked to increased risk for adolescent substance use onset and frequency (Fröjd, Ranta, Kaltiala-Heino, & Marttunen, 2011; Kaplow et al., 2001) and young adult alcohol use disorders (Sartor, Lynskey, Heath, Jacob, & True, 2007). Posttraumatic stress disorder (PTSD) symptoms have been linked to increased risk for alcohol use initiation (Wu, Bird, et al., 2010) and young adult cannabis use disorders (Cornelius et al., 2010); however, further longitudinal studies of PTSD are warranted before the role of PTSD in youth substance use can be determined. Interestingly, adolescent social anxiety has been linked to *decreased* substance use during adolescence (Fröjd et al., 2011), but to *increased* risk for later adult SUDs (Buckner et al., 2008; Zimmermann et al., 2003). Perhaps social anxiety lowers risk for adolescent substance use because socially anxious adolescents are less likely to select into (or to be selected into) peer contexts that promote substance use, but it raises risk for substance use problems during adulthood, when drinking and other substances use is more common and accessible.

Studies examining negative affect pathways to adolescent substance use also highlight the importance of various moderators, suggesting that internalizing processes may play a larger role for a subset of vulnerable youth. For instance, the effects of stress and negative affect on substance use may be stronger for adolescents with various genetic predispositions (e.g., Audrain-

McGovern, Lerman, Wileyto, Rodriguez, & Shields, 2004; Covault et al., 2007). The association between negative affect and substance use may also be stronger in adolescents who have less social support (Hussong et al., 2001), poorer parental emotion socialization (Hersh & Hussong, 2009), and more positive expectancies about the effectiveness of substance use as a coping mechanism (Hussong, Galloway, & Feagans, 2005; Kassel et al., 2007). Indeed, Sher's (1991) model suggests that the relation between stress or negative affect and substance use should be stronger for those who expect substance use to relieve their emotional distress. Although only a minority of adolescents and young adults report using alcohol to cope with negative affect (1–7% in alcohol studies reviewed by Kuntsche, Knibbe, Gmel, & Engels, 2005), those who do may be at particularly high risk for developing alcohol-related problems and disorders (see Hussong et al., 2011).

Gender may also be an important moderator. Although the literature on gender differences in internalizing pathways to substance use is quite complex, with many contradictory findings, it generally appears that the association between negative affect and substance use may be stronger for girls than for boys (Armstrong & Costello, 2002; Mason et al., 2007; Poulin, Hand, Boudreau, & Santor, 2005). However, boys with *early-onset* depression appear to be at markedly high risk for substance use problems, compared to girls and nondepressed boys (Crum, Storr, Ialongo, & Anthony, 2008; Kovacs, Obrosky, & Sherrill, 2003). Researchers have theorized that early mood symptoms may be more likely to manifest themselves subsequently as mood disorders for girls, whereas subsequent substance use and SUDs are more likely for boys (Klein & Corwin, 2002).

Finally, the effects of stress and negative affect on substance use may also be mediated and/or moderated by individual differences in response to stress. For instance, stress/negative affect mechanisms may be stronger for adolescents who use maladaptive coping strategies (e.g., Kassel, Jackson, & Unrod, 2000; Laurent, Catanzaro, & Callan, 1997; Wills, Sandy, Yaeger, Cleary, & Shinar, 2001), who have ruminative stress response styles (Skitch & Abela, 2008), and who have dysregulated biological stress response systems (De Bellis, 2002; Schepis, Rao, Yadav, & Adinoff, 2011). Importantly, research has also shown that early trauma and chronic stress may lead to dysregulation of the hypothalamic–pituitary–adrenocortical axis and other neurobiological mechanisms underlying stress regulation, which may increase risk for early initiation of substance use and later SUDs (Andersen & Teicher, 2009; De Bellis, 2002). Therefore, early adversity may have long-lasting implications for developmental trajectories of substance use via stress-induced changes to the brain that increase vulnerability to stress and negative affect.

THE SUBSTANCE USE EFFECTS SUBMODEL

The discussions above of the deviance-proneness submodel and the stress and negative affect submodel of adolescent substance use serve to illustrate the importance of considering some of the functions that substance use might serve for adolescents. The deviance-proneness submodel highlights the fact that adolescent substance use occurs in a broader social context of low behavioral constraint and drug-use-promoting peer networks. Within these peer social networks, adolescent substance use may serve to communicate a social image of toughness and precocity, and to express an adolescent's actual or ideal self-concept (Barton, Chassin, Presson, & Sherman, 1982; Jessor & Jessor, 1977; Sussman, Dent, & McCullar, 2000). Moreover, the acquired preparedness model suggests that disinhibition biases the learning process, so that impulsive and sensation-seeking adolescents will be more likely to focus on positive substance use effects (see, e.g., Corbin, Iwamoto, & Fromme, 2011). The stress and negative affect submodel highlights the affect-regulating functions that alcohol and drug use may fulfill for adolescents. As such, it is important to remember that alcohol and drug consumption involves reinforcing pharmacological effects, and to consider these effects within etiological models of adolescent SUDs. Sher's (1991) substance use effects submodel is depicted in Figure 4.3. In this model, a family history of alcoholism (or, in our extrapolation, other SUDs) is thought to be associated with individual differences in sensitivity to the pharmacological effects of alcohol and other drugs (as well as with the temperamental and cognitive variables discussed earlier). As people experience different effects of their substance use, these experiences then influence their expectancies about the effects of future consumption. These expectancies in turn influence the likelihood of future substance use involvement.

A large literature has examined the effects of alcohol and drug self-administration in both human and animal laboratory studies, and this literature is beyond the scope of the current chapter. Moreover, for ethical

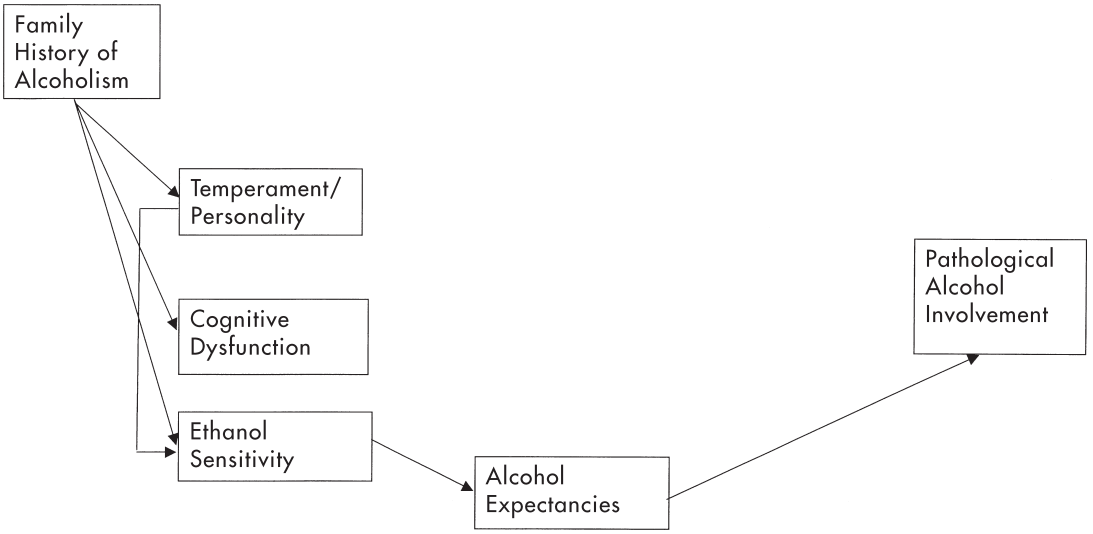

FIGURE 4.3. Schematic diagram of Sher's (1991) substance use effects submodel. From Sher (1991). Copyright 1991 by University of Chicago Press. Adapted by permission.

reasons, human laboratory studies of alcohol or drug administration have been confined to adult participants, so that little is known about the relation between alcohol or drug effects in the laboratory and adolescent alcohol or drug use in the natural environment. Rather, researchers who are interested in child and adolescent populations have focused on their beliefs or expectancies about substance use effects. These expectancies can be measured in young children even before substance use begins, and they become increasingly complex and more positive in adolescence (Dunn & Goldman, 1996). Moreover, adolescents' expectancies about substance use effects are systematically related to their consumption. For example, adolescents' expectancies that alcohol has positive effects prospectively predict their drinking behavior (Smith, Goldman, Greenbaum, & Christiansen, 1995; Stacy, Newcomb, & Bentler, 1991), and expectancies concerning marijuana and stimulants are also associated with adolescent drug preferences and drug use (Aarons, Brown, Stice, & Coe, 2001). Finally, in addition to self-reported beliefs and expectancies about substances, studies have assessed adolescents' implicit attitudes (more automatic positive and negative associations to substances) that are measured indirectly by tasks such as reaction times to pair substance use stimuli with positive and negative words. Measures of more automatic associations have prospectively predicted adolescents' cigarette use (Sherman, Chassin, Presson, Seo, & Macy, 2009) and changes in cannabis use (Cousijn, Goudriaan, & Wiers, 2011), and dual-process models of adolescent substance use propose that the effects of automatic associations are particularly powerful when processes of reflective, cognitive control are weakened (see Wiers et al., 2010).

NEIGHBORHOODS AND OTHER MACRO-LEVEL INFLUENCES

Sher's (1991) deviance-proneness, stress and negative affect, and substance use effects submodels do not explicitly focus on the effects of social influences that are broader than peer and family environments. However, researchers have become increasingly interested in ways in which broader, macro-level environments such as neighborhoods, schools, and SES might influence adolescent substance use and SUDs (mirroring broader trends in the study of macro-level influences on developmental psychopathology). It is likely that these macro-level influences interact with parenting and peer variables, the family environment, personality characteristics, and other etiological factors to influence

adolescent substance use. Neighborhoods, schools, and other social contexts could influence risk for substance use and disorder by providing social norms about the relative acceptability of use, by providing different ease of access to different substances, and by providing different degrees of punishment or sanctions for use. Theoretically, these factors would influence the prevalence of use for adolescents in all three of Sher's etiological pathways.

Several neighborhood characteristics have been linked to increased substance use among youth, including alcohol outlet density, lack of neighborhood strength (e.g., lack of community identity, lower participation in local activities), residential mobility and instability, high population density, high levels of crime or violence, and positive community norms about substance use (Buu et al., 2009; Gibbons, Gerrard, Wills, Brody, & Conger, 2004; Huckle, Huakau, Sweetsur, Huisman, & Caslwee, 2008; Lambert et al., 2004; Leventhal & Brooks-Gunn, 2000; Tobler, Komro, & Maldonado-Molina, 2009; Wilson, Syme, Boyce, Battistich, & Selvin, 2005).

Although neighborhoods with high concentrations of ethnic minorities are often characterized as disadvantaged and high-risk, research indicates that minority youth are generally *less* likely to use alcohol and other substances than are European American youth (SAMHSA, 2001). Some studies suggest that ethnic differences in youth substance use are more likely to be explained by differences in family and peer processes than by compositional characteristics of neighborhoods. For instance, lower rates of substance youth among both Hispanic American (Cox, Burr, Blow, & Parra Cardona, 2011) and African American (Watt & Rogers, 2007) youth have been linked to a greater emphasis on family relationships and lower susceptibility to peer influences. It should be noted, however, that higher levels of acculturation have been shown to erode some of these protective factors for Hispanic American youth (Cox et al., 2011).

Schools are also an important social context for the development of substance use. For instance, research indicates that risk for substance use and SUDs is higher for adolescents who attend schools where substance use is perceived as normative and socially acceptable, and where low levels of school connectedness and poor student–teacher relationships exist (Bond et al., 2007; Botticello, 2009; Fletcher, Bonell, & Hargreaves, 2008). Similarly, school intervention studies have shown that increasing school participation, improving relationships between students and adults (e.g., teachers, coaches) at school, increasing enjoyment and interest in school, and reducing truancy may effectively reduce substance use, especially for boys (Fletcher et al., 2008). In regard to school policies about substance use, consistent enforcement of school antismoking policies has been linked to reduced youth tobacco use, although little is known about how school policies on alcohol and other drugs influence use (Evans-Whipp et al., 2004).

In addition to factors such as neighborhoods, schools, and SES, adolescent substance use is also shaped by public policies, particularly with respect to legal drugs (i.e., alcohol and tobacco). Research has shown that increases in alcohol (Chaloupka, Grossman, & Saffer, 2002) and cigarette taxes/prices (Carpenter & Cook, 2008) significantly reduce youth drinking and smoking. Likewise, increasing the minimum drinking age, lowering the allowable blood alcohol concentration for drivers under the age of 21, regulating the density of alcohol and tobacco outlets, limiting the proximity of alcohol and tobacco outlets to schools, and reducing the permissible volume of alcohol and tobacco advertising/media exposure have all been linked with reduced youth alcohol (Anderson, Chisholm, & Fuhr, 2009; Paschall, Grube, & Kypri, 2009) and tobacco (Henriksen et al., 2008) use and consequences.

CONCLUSIONS AND FUTURE DIRECTIONS

As illustrated by the discussion above, much is known about the nature of adolescent substance use and SUDs, as well as about etiological factors; moreover, much effort has already gone into the development of empirically evaluated treatment and prevention programs. For example, a large and diverse literature has produced a consensus across studies that a family history of SUDs, childhood conduct problems, temperament or personality traits reflecting behavioral undercontrol, and affiliations with drug-using peer networks all raise risk for substance use and SUDs.

However, there are also many unanswered questions and areas for future research. The adequacy of existing diagnostic criteria as they are applied to adolescents must be clarified, and the impact of the two-symptom threshold in DSM-5 requires evaluation. In regard to etiology, although the role of family history risk is well established, less is known about the mechanisms underlying the intergenerational transmission of risk, or about the protective factors that might

buffer this risk. The increasing number of genetically informative studies has suggested that a heritable predisposition to behavioral undercontrol is an important risk factor, and more needs to be known about G×E in the externalizing and internalizing developmental pathways. In terms of externalizing pathways, recent studies have reinforced the notion that behavioral undercontrol is a complex and multifaceted concept. More needs to be known about different aspects of behavioral undercontrol, how they develop, how malleable they are by environmental influences, and how they are related to adolescent substance use outcomes. A better understanding of the multiple processes that drive overall performance in laboratory decision-making and risk-taking tasks is also needed. In regard to the internalizing pathway, studies are needed to clarify its role in the context of strong externalizing effects, and to clarify the roles of different types of negative affect (particularly the importance of moderating variables, including coping and behavioral undercontrol). That is, rather than considering internalizing and externalizing pathways in isolation, it may be more useful to focus on behavioral undercontrol and underregulation as moderators of the relation between environmental stress or negative affect and subsequent substance use outcomes. In general, our understanding of adolescent substance use will benefit from research advances in studying the development of emotional, cognitive, and behavioral self-regulation.

Moreover, in studying these etiological models, it is important to retain a developmental perspective. Recent studies have begun to illuminate ways in which early adversity might influence later deficits in self-regulation (including G×E), which can in turn increase risk for adolescent substance use disorders. Similarly, adolescent substance use itself may further contribute to risk because of particular neurobiological sensitivity to substance use effects, and more data are needed about the magnitude and duration of the effects of substance use on adolescent neurobiological development. For all the etiological models, data are also needed about ways in which our existing findings might vary across particular gender and ethnic subgroups. Moreover, this topic is in need of stronger theory development, which would help guide our interpretations of why particular risk or protective factors might operate in particular ways within certain gender or ethnic subgroups. Beyond questions of gender and ethnic variation, the examination of other macro-level societal and cultural factors (neighborhood effects, school effects, and effects of social policies like taxation) has often been conducted in isolation from more individual-level factors. Research is needed to study neighborhood, school, and social policy influences as they interact with individual, family, and peer factors.

Finally, as is evident from our review, it is unlikely that a single etiological pathway will be capable of explaining the development of adolescent SUDs. Thus we are in need of studies and methods that are capable of differentiating among multiple pathways that might underlie different trajectories of substance use. To accomplish these ambitious goals requires studies that are multilevel and multidisciplinary, and that embed studies of SUDs within a broader developmental perspective. Given the clinical and public health importance of adolescent substance use and SUDs, it is likely that the field will continue to expand in these future directions.

PART III

MOOD DISORDERS AND SUICIDE

CHAPTER 5

Child and Adolescent Depression

CONSTANCE L. HAMMEN
KAREN D. RUDOLPH
JAMIE L. ABAIED

DEFINING CHILD AND ADOLESCENT DEPRESSION

Joey is a 10-year-old boy whose mother and teacher have shared their concerns about his irritability and temper tantrums displayed both at home and at school. With little provocation, he bursts into tears, yells, and throws objects. In class, he seems to have difficulty concentrating and seems easily distracted. Increasingly shunned by his peers, he plays by himself at recess—and at home, spends most of his time in his room watching TV. His mother notes that he has been sleeping poorly and has gained 10 pounds over the past couple of months from constant snacking. A consultation with the school psychologist has ruled out learning disabilities or attention-deficit/hyperactivity disorder (ADHD); instead, she says, he is a deeply unhappy child who expresses feelings of worthlessness and hopelessness—and even a wish that he would die. These experiences probably began about 6 months ago when his father—divorced from the mother for several years—remarried and moved to another town, where he spends far less time with Joey.

Diagnostic Criteria

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013) provides essentially the same criteria for major depressive disorder (MDD) for both adults and children. The criteria are shown in Table 5.1. Persistent depressive disorder (dysthymic disorder) is a diagnosis of chronic, mild to moderate depressive (or for children, irritable mood) symptoms, with a duration of at least 1 year (in adults, duration is at least 2 years). With the new category of persistent depressive disorder, DSM-5 differs from DSM-IV, which defined chronic major depression and dysthymic disorder in separate sections; DSM-5 now emphasizes *persistence* rather than severity. Even the fairly mild symptoms typical of persistent depressive (dysthymic) disorder beginning in childhood or adolescence do not mean that it is a relatively benign condition, however. Such chronic symptoms commonly predict the development of major depressive episodes (MDEs), and may predict a long-term course with significant psychosocial impairment—especially if the symptoms are associated with familial depression and poor parent–child relationships, as is often the case (Klein, Shankman, & Rose, 2008).

In recognition that irritability is a common expression of distress in depressed youngsters (as shown in the case of Joey), DSM-5 specifies that irritable mood may be substituted for depressed mood. However, irritability occurring in MDEs or persistent depressive (dysthymic) disorder is to be distinguished from a new DSM-5 depressive disorder, disruptive mood dysregula-

TABLE 5.1. DSM-5 Diagnostic Criteria for Major Depressive Disorder

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
Note: Do not include symptoms that are clearly attributable to another medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day.
(**Note:** In children, consider failure to make expected weight gain.)
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly ever day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiological effects of a substance or to another medical condition.

Note: Criteria A–C represent a major depressive episode.

Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

E. There has never been a manic episode or a hypomanic episode.
Note: This exclusion does not apply if all of the manic-like or hypomanic-like episodes are substance-induced or are attributable to the physiological effects of another medical condition.

Coding and Recording Procedures

The diagnostic code for major depressive disorder is based on whether this is a single or recurrent episode, current severity, presence of psychotic features, and remission status. Current severity and psychotic features are only indicated if full criteria are currently met for a major depressive episode. Remission specifiers are only indicated if the full criteria are not currently met for a major depressive episode.

In recording the name of a diagnosis, terms should be listed in the following order: major depressive disorder, single or recurrent episode, severity/psychotic/remission specifiers, followed by as many of the following specifiers without codes that apply to the current episode.

Specify:

With anxious distress
With mixed features
With melancholic features

(continued)

TABLE 5.1. *(continued)*

With atypical features
With mood-congruent psychotic features
With mood-incongruent psychotic features
With catatonia
With peripartum onset
With seasonal pattern

tion disorder, which was intended to provide an alternative to the excessive diagnosis of bipolar disorders in children when the presentation is marked by severe and persistent temper outbursts and irritability rather than classic episodic mood changes (for further discussion, see Youngstrom & Algorta, Chapter 6, this volume). Disruptive mood dysregulation disorder in children is defined by pronounced and frequent temper outbursts, with rage, aggression, and persistently angry mood (see Table 5.2). Evidence of its validity as a depressive disorder is scant at present, however, and critics have argued that it may not be either distinguishable from oppositional defiant disorder or conduct disorder, or predictive of a depressive course (e.g., Axelson et al., 2012).

TABLE 5.2. DSM-5 Diagnostic Criteria for Disruptive Mood Dysregulation Disorder

A. Severe recurrent temper outbursts manifested verbally (e.g., verbal rages) and/or behaviorally (e.g., physical aggression toward people or property) that are grossly out of proportion in intensity or duration to the situation or provocation.
B. The temper outbursts are inconsistent with developmental level.
C. The temper outbursts occur, on average, three or more times per week.
D. The mood between temper outbursts is persistently irritable or angry most of the day, nearly every day, and is observable by others (e.g., parents, teachers, peers).
E. Criteria A–D have been present for 12 or more months. Throughout that time, the individual has not had a period lasting 3 or more consecutive months without all of the symptoms in Criteria A–D.
F. Criteria A and D are present in at least two of three settings (i.e., at home, at school, with peers) and are severe in at least one of these.
G. The diagnosis should not be made for the first time before age 6 years or after age 18 years.
H. By history or observation, the age at onset of Criteria A–E is before 10 years.
I. There has never been a distinct period lasting more than 1 day during which the full symptom criteria, except duration, for a manic or hypomanic episode have been met.
   Note: Developmentally appropriate mood elevation, such as occurs in the context of a highly positive event or its anticipation, should not be considered as a symptom of mania or hypomania.
J. The behaviors do not occur exclusively during an episode of major depressive disorder and are not better explained by another mental disorder (e.g., autism spectrum disorder, posttraumatic stress disorder, separation anxiety disorder, persistent depressive disorder [dysthymia]).
   Note: This diagnosis cannot coexist with oppositional defiant disorder, intermittent explosive disorder, or bipolar disorder, though it can coexist with others, including major depressive disorder, attention-deficit/hyperactivity disorder, conduct disorder, and substance use disorders. Individuals whose symptoms meet criteria for both disruptive mood dysregulation disorder and oppositional defiant disorder should only be given the diagnosis of disruptive mood dysregulation disorder. If an individual has ever experienced a manic or hypomanic episode, the diagnosis of disruptive mood dysregulation disorder should not be assigned.
K. The symptoms are not attributable to the physiological effects of a substance or to another medical or neurological condition.

Developmental differences in the expression of depressive symptoms have been noted, even if these are not codified in the formal diagnostic criteria. As summarized by Avenevoli, Knight, Kessler, and Merikangas (2008; see also Rao & Chen, 2009), somatic complaints are more common among younger samples, who also express less subjective dysphoria and hopelessness; hypersomnia increases during adolescence, and appetite decreases (in girls). Depressed boys are at the greatest risk of suicidal behaviors in late adolescence, whereas girls are at the highest risk during middle adolescence. Yorbik, Birmaher, Axelson, Williamson, and Ryan (2004) compared the symptoms of nearly 900 depressed children and adolescents, and found that depressed adolescents exhibited significantly more fatigue, hypersomnia, suicidal thoughts and attempts, hopelessness/helplessness, and weight loss than children.

It is possible that additional research on developmental expressions of depression will suggest further age-appropriate modifications of the diagnostic criteria. For example, a longitudinal study of MDD in preschoolers found that although the DSM-IV criteria validly defined a group of young children with depression and homotypic continuity into early childhood (Luby, Si, Belden, Tandon, & Spitznagel, 2009), the minimum duration and frequency criteria might not necessarily apply. Children who met full symptom criteria but not duration and frequency did not differ in severity, impairment, or risk of MDD 2 years later (Gaffrey, Belden, & Luby, 2011). Further study of developmentally relevant modifications is needed, and potential alterations may be especially important for significant but subclinical cases that might otherwise not be identified.

Like adult depression, childhood depression sometimes includes psychotic symptoms and endogenous (melancholic) features indicative of severe depression. However, the symptom manifestations that have attracted most attention among children and adolescents are suicidal thoughts and actions, which are commonly but not exclusively associated with depressive disorders (see Cha & Nock, Chapter 7, this volume). The topic has attracted widespread attention for two reasons. First, the U.S. Food and Drug Administration issued a "black box" warning of suicidality as an alleged side effect of antidepressant medications among children, adolescents, and young adults; a discussion of this is beyond the scope of this chapter (but see *www.nimh.nih.gov/health/topics/child-and-adolescent-mental-health/antidepressant-medications-for-children-and-adolescents-information-for-parents-and-caregivers.shtml*). Second, suicidality certainly underscores the severity and lethality of depressive disorders, reminding us that these disorders are serious problems and not merely expressions of youthful turmoil. A review by Bridge, Goldstein, and Brent (2006) notes that suicidal ideation is very common in adolescence with reported point prevalence rates of 15–25%, whereas actual suicide attempts occur in 1–4% of adolescent males and 1.5–10% of females. Completed suicides increase in frequency from childhood to older adolescence, and are considerably higher in males than in females (e.g., 17% for males vs. 3% for females among older adolescents in the United States). Depressive disorders appear to be present in approximately 40% of completed suicides, and even higher rates are seen in youth for whom depression is comorbid with substance use and disruptive behavior disorders (Bridge et al., 2006). Rates of depression have been reported as 40–80% among those who attempt suicide (Cash & Bridge, 2009). In samples of clinically referred youth with depressive disorders, 85% report suicidal ideation, and 32% make a suicide attempt during adolescence or young adulthood (Kovacs, Goldston, & Gatsonis, 1993).

Continuity of Depression Severity

Depression in its "clinical" forms is represented by diagnostic categories as discussed thus far, but DSM classifications, despite their value in improving reliability and communicability, have the disadvantage of implying that individuals either do or do not "have" the disorders in question. In the context of depression, taxometric analyses of the latent structure of DSM-IV MDD symptoms in a sample of 845 youth (ages 9–17) suggested that depression is continuously, rather than categorically, distributed for both children and adolescents and boys and girls (Hankin, Fraley, Lahey, & Waldman, 2005). These authors recommend dimensional assessment of the severity of depression in order to fully capture the phenomena. Importantly, subsyndromal or subclinical depressions that fall short of full diagnostic criteria may nevertheless predict negative outcomes and commonly warrant intervention. Among adults, for example, subclinical levels of symptoms and minor depression portend degrees of functional impairment and use of services often approximating those of individuals with MDD (e.g., Backenstrass et al., 2006; Cuijpers, de Graaf, & van Dorsselaer, 2004). In a youth sample, subclinical depression at ages 17–18 predicted

elevated rates of MDD and depressive symptoms and other disorders (as well as treatment seeking) in two subsequent follow-ups to age 25, compared to those without depressive symptoms (Fergusson, Horwood, Ritter, & Beautrais, 2005; see also Shankman et al., 2009).

Many of the studies of depression in children and adolescents reported in this chapter do not rely on diagnostic assessments, but instead are based on elevated scores on a continuous measure of depression severity covering various symptoms of the syndrome. Commonly used self-report scales are the Children's Depression Inventory (Kovacs, 1980) and the Center for Epidemiologic Studies Depression Scale (Radloff, 1977), both well-validated measures of severity of depressive symptoms, although questions arise about their specificity to depression versus more general negative affect. Similar to studies of clinical compared to subclinical diagnoses, a youth's high scores on self-report measures may portend significant clinical and functional impairment even if the person is not diagnosable (e.g., Gotlib, Lewinsohn, & Seeley, 1995). Use of the self-report Patient Health Questionnaire for Depression (Kroenke & Spitzer, 2002), which assesses the presence of the nine MDD symptoms and has been adapted for children and adolescents, has been recommended in DSM-5 as a supplement to diagnostic evaluation, providing a continuous score of severity of depression.

Clinical Course of Depression

Age of Onset

The prototypical depression is MDD with adolescent onset. In the National Comorbidity Survey Replication—Adolescent Supplement (NCS-A), the median age of onset for DSM-IV mood disorders was 13 (Merikangas et al., 2010). Retrospective assessment among community adults typically indicates that middle to late adolescence is the most common age of onset for a first episode of MDD or significant symptoms (e.g., Burke, Burke, Regier, & Rae, 1990; see also Kessler, Berglund, Demler, Jin, & Walters, 2005). In their community sample, Lewinsohn, Pettit, Joiner, and Seeley (2003) reported mean onset of MDD at around 14 years and mean onset of dysthymic disorder at around 11 years for both boys and girls. As discussed in the section on gender and depression, early adolescence is the point at which the rates of major depression increase sharply for girls and exceed depression rates in boys.

Age of onset appears to be an important potential marker for the course of a depressive disorder and the possibility of etiologically different subtypes. Compared to childhood onset, adolescent onset predicts greater homotypic continuity, whereas childhood onset is more commonly associated with heterotypic continuity. For example, Weissman, Wolk, Wickramaratne, and colleagues (1999) followed a clinically ascertained group of prepubertally depressed youngsters for 10–15 years into adulthood, and found that the majority did not go on to have adult depressive experiences. These youngsters had high rates of psychological disorders and significant maladjustment, but there was poor specificity for depressive disorders. Similar results were reported by Harrington, Fudge, Rutter, Pickles, and Hill (1990) in a follow-back study of the adult functioning of individuals who had been treated for depression as children or adolescents. Thus, across these studies, *childhood* onset of depression may predict significant disorder but not specifically recurring depression, except in subsamples characterized by less comorbidity, recurrent MDDs, and family history of depression. Many children presenting with depression plus externalizing disorders may have an etiologically different depression, or actually may not have depressive disorder as such, but rather suffer from marked emotional and behavioral dysfunction that eventually coalesces into nondepressive psychopathology. As reported later in the section on genetic factors in depression, studies of heritability typically find much stronger evidence of heritability for adolescent-onset depression (similar to adult depression) than for childhood onset (e.g., Rice, 2010).

Recurrence

Data on continuity of *adolescent* depressive disorders into adulthood are strongly consistent and underscore the premise that much depression seen in adults is actually recurrent adolescent-onset depression. Several large-scale prospective community samples reported on the outcomes in young adulthood of those who had been found to have a diagnosis of MDD during adolescence. The Queensland High Risk Study (Hammen, Brennan, Keenan-Miller, & Herr, 2008), the Dunedin (New Zealand) Multidisciplinary Health and Development Study (Bardone, Moffitt, Caspi, Dickson, & Silva, 1996), the Ontario Child Health Study (Fleming, Boyle, & Offord, 1993), the Oregon Adolescent Depression Project (Lewinsohn, Rohde, Klein, & Seeley, 1999),

and the Upstate New York study (Pine, Cohen, Gurley, Brook, & Ma, 1998) all reported high rates of recurrence of MDD in young adulthood (approximately 25–45% within 4 years). Recurrence rates of 40–60% are typical of clinically ascertained samples. A large-scale 10-year study of clinic-referred adolescents followed up to a mean age of 26 found that only 37% survived without an episode of MDD in adulthood (Weissman, Wolk, Goldstein, et al., 1999).

Among those with childhood onset of depression, true childhood-onset unipolar depression is relatively rare, but appears to be associated with a high risk of recurrence; many with unipolar depression have been found to have early-onset dysthymic disorder followed by MDEs (so-called "double depression"), as well as a high degree of depressive disorders in relatives (Birmaher et al., 2004; Kovacs, Akiskal, Gatsonis, & Parrone, 1994; Kovacs, Devlin, Pollock, Richards, & Mukerji, 1997; Weissman, Wolk, Wickramaratne, et al., 1999). Several studies have found a strong association between childhood anxiety symptoms and inhibited or withdrawn behavior, and later anxiety and depressive disorders (e.g., Goodwin, Fergusson, & Horwood, 2004; Katz, Conway, Hammen, Brennan, & Najman, 2011).

It should be noted that a significant minority of children initially (mis)diagnosed with unipolar depression in clinical settings eventually evidence hypomania or mania, which enables a bipolar disorder to be diagnosed (reviewed in Kovacs, 1996; see Youngstrom & Algorta, Chapter 6, this volume). For instance, Kovacs, Akiskal, Gatsonis, and Parrone (1994) found that 13% of their sample initially diagnosed with depression "switched" to bipolar disorder if followed long enough. Geller, Fox, and Clark (1994) found that among a clinical sample of severely depressed children (ages 6–12), 32% switched to bipolar I or II during a 2- to 5-year follow-up. Although symptom predictors of switching have yet to be validated, having a family member with a bipolar disorder increases the likelihood that a child's depression may be an early manifestation of a bipolar disorder. Biederman and colleagues (2009) found that depressed children and adolescents with comorbid ADHD or conduct disorder at baseline also had an increased likelihood of eventual bipolar diagnoses.

Comorbidity

The co-occurrence of disorders has attracted considerable attention in recent years, and comorbidity has now become widely recognized as the rule rather than the exception among depressed youngsters. Community studies permit the best tests of comorbidity rates, inasmuch as clinical populations may be biased because treatment seeking is more common among those with multiple conditions, which in turn are associated with greater impairment of functioning. In a large British community survey, children ages 5–15 with depression were most likely of those with any disorder to have at least one current comorbid diagnosis (66%) (Ford, Goodman, & Meltzer, 2003). Depressed children and adolescents are especially likely to experience anxiety disorders, but also conduct/behavioral disorders, as well as substance use disorders (in adolescents). Angold, Costello, and Erkanli (1999) conducted a meta-analysis of comorbidity in community studies of youngsters and reported a median odds ratio (degree of association) of 8.2 for depression and anxiety disorders, 6.6 for depression and conduct/oppositional defiant disorder, and 5.5 for depression and ADHD. It should be noted that patterns of comorbidity and timing of disorders may differ somewhat by developmental stage and gender (see O'Neil, Conner, & Kendall, 2011; Zahn-Waxler, Shirtcliff, & Marceau, 2008).

To a considerable extent, depression usually occurs after an earlier-onset disorder. A particularly striking case is that of anxiety disorders. Rohde (2009) reported that anxiety disorders occurred first in 85% of youth with comorbid depressive/anxiety disorders (see also Essau, 2003), although depression also may be followed by anxiety disorders in some cases. Externalizing disorders often have earlier onset than comorbid depressive disorders, although the pattern is variable across studies (Rohde, 2009). Kessler, Avenevoli, McLaughlin, and colleagues (2012) retrospectively evaluated temporal patterns of disorders in the NCS-A: They factor-analyzed disorders into classes labeled Fear (e.g., social and specific phobia, panic disorder), Distress (generalized anxiety or separation anxiety disorders and depressive disorders), Behavior (e.g., oppositional defiant disorder, conduct disorder, ADHD), and Substance disorders. The investigators determined that within-class associations were significantly stronger than cross-class associations (e.g., Distress disorders predicted other Distress disorders). Fear disorders were the strongest cross-class predictors, consistent with the common observation of early-onset anxiety disorders preceding depressive disorders.

The magnitude of depression comorbidity raises important clinical, conceptual, and methodological questions. Clinically, the presence of comorbid conditions

with depression predicts greater impairment of functioning, sometimes elevated rates of suicidal behavior, and greater treatment utilization, but less successful treatment outcomes (reviewed in Rohde, 2009). Conceptually, extensive comorbidity means that research findings attributed to depression may sometimes reflect effects due to unreported comorbid conditions or to the greater severity/impairment typically associated with comorbidity. The high rates of comorbidity have been variously hypothesized to arise from deficiencies in the diagnostic system, such as overlapping symptoms, shared etiological factors, or a functional relationship between disorders (e.g., disruptive behavior disorders may cause stressful consequences that provoke depressive reactions). Notably, there are significant bodies of research on shared etiological features of depression and anxiety disorders (e.g., genetic, personality/temperament, and neurotransmitter/neurocognitive factors), and on differentiating shared and unique predictive factors (e.g., Anderson & Hope, 2008; Clark & Watson, 1991).

A full discussion of the origins and meaning of depression comorbidity is beyond the scope of the present chapter. However, it is worth noting the emergence of analytic and assessment strategies to deal with the joint problems of the heterogeneity of the depression phenotype and diagnostic comorbidity, which are barriers to precision in the understanding of depression and its unique risk factors and consequences. Of relevance to depression is the use of quantitative approaches to aggregating manifest DSM diagnoses into superordinate categories, based on the assumption that disorders within the superordinate category reflect a common cause. Numerous studies mostly on adults have supported general internalizing and externalizing factors (e.g., Eaton et al., 2012; see Krueger & Markon, 2006), but Kessler, Avenevoli, McLaughlin, and colleagues (2012) also demonstrated the broad internalizing factor among adolescents with diagnoses may be subdivided into Fear and Distress factors. Such transdiagnostic approaches to the study of child and adolescent depression/anxiety might yield new insights beyond those of studies more narrowly focused on specific DSM diagnoses. In addition, the National Institute of Mental Health has developed the Research Domain Criteria (Sanislow et al., 2010) as a research strategy intended to study specific functions across multiple units of analysis, to cut across diagnostic boundaries, and to try to translate basic research into an improved and integrative understanding and treatment of psychopathology. This strategy is somewhat similar to the search for "endophenotypes" or "intermediate phenotypes." An endophenotype is the more specific representation or element of a disorder that is between the disease and likely distal heritable aspect of the mechanism of the disorder but is not the same as the diagnostic entity. In youth depression, for example, bias toward negative emotions (negative mood), or impaired reward functioning (anhedonia), or a particular biological function such as amygdala reactivity to emotional stimuli are a potential endophenotype that might provide a more focused target of study independent of the diagnostic heterogeneity of MDD and comorbidity (e.g., Hasler, Drevets, Manji, & Charney, 2004). Further developments in our understanding of youth depression are likely to require assessment strategies and case identification methods that go beyond use of DSM categories.

Summary

Depressive disorders and significant symptoms in children and adolescents often portend serious psychological and functional adjustment problems—sometimes recurring depression, but other times different forms of maladjustment into later adolescence and adulthood. Adolescent-onset depression is virtually the "prototype" of what we mean by MDD in adults. However, the differences among presentations of depression by age, clinical features, comorbidities, and outcomes are obstacles to research. Thus further study of developmentally appropriate diagnostic and assessment methods, as well as both transdiagnostic and endophenotypic approaches to characterization of the phenomena, are warranted.

EPIDEMIOLOGY

Prevalence/Incidence

Recent years have seen an increase in epidemiological surveys of child and adolescent disorders using diagnostic interviews and representative samples, although variations in assessment and informant methods have precluded precise comparability across studies. A review of 28 U.S. and international surveys using standardized diagnostic criteria was reported by Avenevoli and colleagues (2008), who found a range of 2–13% in 6- or 12-month prevalence of MDD among adolescents (approximately 13–18 years), and about 1–3% among

school-age children (7–12 years). The NCS-A, the largest and most nationally representative U.S. diagnosis-based survey, reported a 12-month prevalence rate of 8.2% for MDD or dysthymia in the 13- to 17-year-old sample (Kessler, Avenevoli, Costello, Georgiades, et al., 2012); about one-third of adolescents with depression were characterized as having "severe" cases, as defined by functional impairment represented by a score of 50 or less on the Children's Global Assessment Scale (Kessler, Avenevoli, Costello, Green, et al., 2012). Merikangas and colleagues (2010) reported a lifetime rate of 11.7% with MDD or dysthymia in the NCS-A, including 8.7% with severe depression. Avenenvoli and colleagues (2008) found that rates of dysthymia are typically are higher than those of MDD among children, but lower than those of MDD among adolescents.

Epidemiological samples also report markedly high rates of elevated depressive symptoms. A U.S. school-based survey of 11-to 15-year-olds obtained self-reports of DSM criteria for MDE in the past 12 months, and found that 18% of youth overall met the criteria (25% females, 10% males; Saluja et al., 2004). In the National Longitudinal Study of Adolescent Health of youth in grades 7–12 (AddHealth), 29% of youth reported depressive symptoms for the past week meeting the "moderately severe" cutoff of 16 on the Center for Epidemiologic Studies Depression Scale, and 9% met the "severe" cutoff of >24 (Rushton, Forcier, & Schectman, 2002). One year later, 44% of youth with severe symptoms continued to report the same high levels.

Gender, Socioeconomic, and Race/Cultural Differences in Depression

Besides evidence for higher rates of depression among adolescents than children, other notable epidemiological issues concern distributions by gender and additional sociodemographic factors. Most studies indicate that boys and girls have largely similar rates of depression in childhood, but by early adolescence, girls' rates of depressive disorders accelerate dramatically to approximately twice the rates as for boys, and the female–male gender difference remains throughout adulthood and occurs cross-nationally (e.g., Kessler, Avenevoli, Costello, Georgiades, et al., 2012; Merikangas et al., 2010; Nolen-Hoeksema & Girgus, 1994).

The female preponderance of depression is a significant challenge to theories about the origins of these disorders. Several theoretical perspectives highlight the interactive contribution of sex-linked differences in hormonal and biological functioning, stress-related processes, and interpersonal relatedness to the emerging sex difference during adolescence (e.g., Cyranowski, Frank, Young, & Shear, 2000; Hilt & Nolen-Hoeksema, 2009; Rudolph, 2009). Collectively, these perspectives suggest that complex associations among puberty-linked gonadal hormones and brain neurotransmitters affect mood and biological processes in response to stressful circumstances during adolescence in vulnerable individuals. Risk is also thought to be intensified in girls relative to boys due to girls' greater exposure and reactivity to social challenges during this time (Rudolph, 2002; Shih, Eberhart, Hammen, & Brennan, 2006), which in turn are believed to result from both biological sex differences in affiliative needs and socialization experiences that create a heightened focus on interpersonal connectedness and social-evaluative concerns (Cyranowksi et al., 2000; Hilt & Nolen-Hoeksema, 2009; Rudolph, 2009). Girls also are exposed more often to traumatic sexual abuse experiences, which can further affect their biological and psychological reactivity to social stressors (Hilt & Nolen-Hoeksema, 2009). There are additional differences between the genders in the ways they cope with stressful life events and depressed mood, with women tending to adopt a more passive, internalized, ruminative style that amplifies depressive symptoms, compared to males' more active/distracting and instrumental coping that dissipates negative emotionality (Nolen-Hoeksema, 2000). During the transition through puberty, interpersonal vulnerability, social risk, and normative developmental challenges (e.g., physical-maturational, cognitive-developmental, and social-contextual changes) collectively contribute to the emerging sex difference in depression (Rudolph, 2009). Moreover, this developmental context of risk is particularly salient in girls who progress through puberty earlier than their peers—as reflected in prospective links between early maturation and heightened depressive symptoms—suggesting that puberty and its timing may be more important predictors of the emerging sex difference than chronological age per se (Rudolph, 2014). Clearly, complex, integrative models are necessary to account for the emergence of marked sex differences in rates of depression across adolescence.

Sociodemographic variables that represent relatively adverse environmental conditions also are generally associated with higher rates of depression in adult samples, but the evidence is less consistent for youth (e.g., Kessler, Avenevoli, Costello, Georgiades, et al., 2012).

Poverty was not associated with lifetime depressive disorders in youth in the NCS-A study (Merikangas et al., 2010). In their meta-analysis of depressive symptomatology in adolescent samples, Twenge and Nolen-Hoeksema (2002) found no association between socioeconomic status and depression. Similarly, evidence of systematic differences in depression by race/ethnicity has been mixed, with some studies showing elevated rates of depressive disorders and symptoms in African American, Hispanic/Latino, and Asian American samples compared with European American samples, but other studies showing no differences (e.g., Anderson & Mayes, 2010; Latzman et al., 2011). Higher rates of mood disorders were seen in Hispanic adolescents than in non-Hispanic European American adolescents in the NCS-A lifetime rates (Merikangas et al., 2010). Twenge and Nolen-Hoeksema (2002) also found that Hispanic samples scored higher levels of depressive symptoms than did African American or European American samples. Further studies are needed to explore race and ethnicity effects by addressing methodological shortcomings, and to separate out effects that might be caused by different cultural expressions of depressive symptoms and adverse conditions that could be associated with ethnic status (e.g., Anderson & Mayes, 2010).

Birth Cohort Effects

Earlier reports of birth cohort effects showing higher rates of major depression in those born more recently (e.g., Klerman et al., 1985) have been replicated in the United States and internationally by the Cross-National Collaborative Group (1992), indicating growing rates of childhood or adolescent onset of depression among those born in more recent decades. Results from the original National Comorbidity Study also showed evidence of increasing prevalence of MDEs in those born since 1960 (Kessler, Avenevoli, & Merikangas, 2001). Various analyses of the sources of such increasing rates generally have argued against methodological artifacts as explanations, such as memory or increasing willingness to admit to depressive experiences. Most of the research has been based on retrospective accounts; obviously, longitudinally collected information is needed to examine the issue more directly. Twenge and Nolen-Hoeksema (2002) examined longitudinal studies of depressive symptoms (controlling for age and period effects) and found evidence of decreasing symptoms for boys and no changes for girls, contrary to the findings of earlier retrospective studies. It is likely that rates of depressive disorders did increase among youth in recent years—clearly accompanied by higher rates of treatment seeking, impairment, and suicidality—but whether the effect has now diminished, or was in fact due in significant part to changes in perceptions and awareness of depression, remains unresolved.

ETIOLOGY OF DEPRESSION

Biological Vulnerability to Depression

Brain Structures and Neural Circuitry

Efforts to understand the neural underpinnings of depression have commonly focused on brain structures associated with detecting, responding to, and regulating emotional information—mostly in limbic and cortical circuits, including prefrontal cortex (PFC), amygdala, hippocampal, ventromedial striatum, and related areas. The amygdala is involved in detection of stimuli that are salient for the individual's immediate well-being. Meta-analyses of structural findings have largely confirmed reductions in amygdala *volume* in adults with depression (especially those who are unmedicated), compared with controls (Hamilton, Siemer, & Gotlib, 2008). According to a review of imaging studies of depressed children and adolescents, there is similar but not entirely consistent evidence of amygdala volume differences in depressed and nondepressed youth (Hulvershorn, Cullen, & Anand, 2011); however, certain cortical areas, such as the PFC, orbitofrontal cortex (OFC), and anterior cingulate cortex (ACC), more consistently show volume abnormalities similar to those seen in adult depression.

Smaller amygdala volume is associated with greater responsivity to emotional stimuli. Studies of amygdala *activation* commonly present stimuli such as emotional faces. Depressed adults who were scanned while viewing fearful faces displayed greater amygdala activation compared to nondepressed controls (e.g., Monk, 2008). Similar paradigms generally yield parallel findings in youth, although with small samples and some inconsistencies between child and adolescent samples (Hulvershorn et al., 2011). Yang and colleagues (2010) presented an emotional face-matching task to adolescents with depression and to matched controls, and observed abnormally hyperactive left amygdala in the depressed youth. Increased amygdala activation also has been observed in adolescents at risk for depression due to maternal depression (Monk et al., 2008). Using a neu-

ral activation paradigm, Joormann, Cooney, Henry, and Gotlib (2012) demonstrated that at-risk girls were less successful in cognitive control (i.e., using positive autobiographical memories to "repair" sad mood induced by a film). Compared to the control daughters, the at-risk daughters showed less activation of dorsal areas of the PFC to recruit positive memories to reduce sad mood, and showed sustained greater amygdala activation. The authors speculate that these neural patterns reflect a trait marker stemming from difficulty in regulating negative affect, potentially portending development of depression (especially in the face of stressors). Emotion regulation processes based in limbic–cortical interactions also may be disrupted in youth with very early-onset MDD. Pagliaccio and colleagues (2012) studied school-age children who had experienced preschool onset of depression, using a version of the sad mood elaboration task of Joormann and colleagues, and found similar hypoactivity in areas of the PFC.

It should be noted that research has yet to determine the origins of depression-related cortical–limbic abnormalities—whether they are acquired, genetic, or both. Several studies have demonstrated the role of gene variants in neural correlates of disorder. Studies of both adults and children show increased activation of the amygdala to negative emotional stimuli among those with the short alleles of the serotonin transporter gene (5-HTTLPR; e.g., Furman, Joormann, Hamilton, & Gotlib, 2011; Hariri et al., 2002). Lau and colleagues (2010) found greater amygdala activation to emotional faces among brain-derived neurotrophic factor (BDNF) Met-allele carriers compared to Val/Val homozygotes in a sample of adolescents with depressive or anxiety disorders. Pagliaccio and colleagues (2012) found that severity of initial preschool depression was associated with later dysfunctional brain activity, and hypothesized that the depression symptoms may play a causal role in decreasing ability to effectively exert cognitive or prefrontal control over one's emotions.

Another element of cortical, limbic, and striatal brain regions implicated in emotion-processing neural circuits that are believed to be dysregulated in MDD is the hippocampus (HC), adjacent to the amygdala. The HC plays a major role in consolidation of information into long-term memory as well as in emotional responding, and is an important regulator of PFC function. It contains high levels of glucocorticoid receptors and is involved in the regulation of the hypothalamic–pituitary–adrenocortical (HPA) axis through its projections to the hypothalamus. It is vulnerable to stress-related steroids, which have been speculated to cause HC atrophy under conditions of severe and prolonged stress. Considerable evidence has shown reduced HC volume in depressed adult patients (e.g., Kempton et al., 2011; MacQueen & Frodl, 2011), and HC dysfunction contributes to sustained dysregulation of the stress response. Child and adolescent studies have generally found similar reduced HC volumes (Hulvershorn et al., 2011). Rao and colleagues (2010) found lower HC volumes in both depressed adolescents and at-risk adolescents (due to parental depression), and lower HC volume was associated with higher levels of early life adversity. Chen, Hamilton, and Gotlib (2010) similarly found lower HC volumes in girls ages 9–15 at risk for depression due to maternal depression. Several studies have noted potential genetic and environmental effects on reduced HC volume. For example, Frodl and colleagues (2010) found that adults' reports of childhood stress interacted with the presence of short alleles of the 5-HTTLPR gene to predict hippocampal volume. They speculated that genetic processes predictive of depression partly affect the extent of HC changes in response to stress.

Another conceptual paradigm for studying emotional mechanisms underlying depressive disorders has focused on biological bases of reward processing, involving affective, motivational, and decisional components, behaviorally reflected in depressed individuals' low mood and reduced experiences of pleasure, and biased perceptions of and attention to negative outcomes. Considerable evidence has emerged from task-based imaging studies of abnormalities in the striatum, amygdala, and OFC in depressed adults (e.g., Diekhof, Falkai, & Gruber, 2008). Studies of the reward behaviors and neural patterns of depressed children and adolescence also indicate abnormalities such as blunting of reward-related activation (e.g., Forbes et al., 2009). Similarly, even before the development of depression, girls at risk due to maternal depression displayed abnormal patterns under conditions of reward and loss in the striatum and the dorsal ACC, compared to a no-risk comparison group (Gotlib et al., 2010).

Reward circuitry also has been discussed in terms of asymmetries in PFC function associated with approach- and withdrawal-related mood and emotion, with left-sided hypoactivation associated with depression and reduced perception and pursuit of positive incentives, and right-sided hyperactivation associated with inhibition and anxiety (Davidson, Pizzagalli, Nitschke, & Putnam, 2002). Both infants of depressed

mothers and depressed adolescents display relatively reduced left frontal activation measured by electroencephalogram (reviewed in Davidson et al., 2002). These authors speculate that the interconnections of the PFC and other cortical and subcortical structures represent a dysfunctional circuit in which there is deficient regulation of the amygdala, potentially resulting in prolonged processing of negative affect, and insufficient modulatory control by other cortical functions. These ideas are bolstered by a decade of neuroimaging research, as noted above. However, it is important to acknowledge not only that the childhood/adolescent literature on brain functions is relatively small, but that the origins of abnormal neural structures and circuits are matters of speculation. There also is a paucity of longitudinal research clarifying the developmental course of functional brain abnormalities and their clinical consequences. The potential role of gonadal hormones in the development of depression, for example, is enormously complex, in part due to the crucial links among hormones, brain structures and functions, and neurotransmitters (Blanton et al., 2012).

Hypothalamic–Pituitary–Adrenocortical Axis

Dysregulation of the HPA axis is one of the most robust biological correlates of adult depression, with evidence of elevated cortisol levels, elevated corticotropin-releasing hormone (CRH), and impaired negative feedback control of the HPA axis. It is generally hypothesized that exposure to stressful events and chronic circumstances triggers the development of depression in part through the HPA axis and its associated brain connections, with the supposition that severe and/or early stress exposure may alter neural and HPA axis functioning (e.g., Heim, Newport, Mletzko, Miller, & Nemeroff, 2008). Some individuals also are presumed to have preexisting genetically or environmentally mediated abnormalities in the stress response system, which make them vulnerable to depressive reactions to stress (e.g., Halligan, Herbert, Goodyer, & Murray, 2007).

Earlier studies of child and adolescent depressed samples provided supportive but inconsistent evidence of HPA axis dysregulation, but more recent meta-analyses and reviews have drawn different conclusions. Guerry and Hastings (2011; see also Lopez-Duran, Kovacs, & George, 2009) examined studies based on different methods: dexamethasone suppression, basal cortisol, CRH infusion, psychological challenges, and children of depressed parents. Noting numerous methodological deficiencies, Guerry and Hastings (2011) and Lopez-Duran and colleagues (2009) nevertheless found that when studies were grouped by methods, there was fairly consistent evidence of abnormalities in HPA axis functioning in depressed or at-risk children and youth, including elevations in basal levels of cortisol, greater cortisol response to psychological stressors, and a predictive association between elevated cortisol and later development of depression. Moreover, differences between depressed and nondepressed youth generally appeared to be smaller in scale than between depressed and nondepressed adults, suggesting the need for developmentally informed hypotheses and methods. Indeed, research indicates that baseline cortisol levels and reactivity to stress increase across adolescence and pubertal development (e.g., Gunnar, Wewerka, Frenn, Long, & Griggs, 2009).

Guerry and Hastings (2011) suggested that cortisol differences are particularly observed under stressful conditions, such as laboratory stressors and both acute and chronic stress exposure (including having a depressed mother). Examining cortisol in the context of stressful situations, rather than naturally occurring levels, may improve prediction of future depressive symptoms. In one study, Susman, Dorn, Inoff-Germain, Nottelmann, and Chrousos (1997) found that cortisol reactivity to a stressful situation (blood draw) predicted depressive symptoms 1 year later. In another study, Rudolph, Troop-Gordon, and Granger (2011) found that exposure to the stressful experience of actual peer victimization interacted with heightened anticipatory cortisol while awaiting a laboratory peer-related stressor to predict depressive symptoms 1 year later. These findings suggest that sensitivity of the HPA axis to ongoing stressors, particularly in youth with a history of stress exposure, may serve as a risk factor for subsequent depression.

Adam, Sutton, Doane, and Mineka (2008) also emphasized the need for longitudinal studies of youth prior to the development of depression, and accentuated the importance of the "cortisol awakening response" (CAR, which occurs approximately 40 minutes after waking up) as a particularly potent predictor of future depression onset. Adam and colleagues (2010) found that elevated baseline CAR, but not other measures of cortisol such as bedtime or daily slope, predicted a significantly increased rate of depressive disorder over the next year in a community sample of late adolescents. It was suggested that the CAR measure is uniquely pre-

dictive of future depression, whereas other measures of cortisol functioning covary with current depression. Because the CAR marks the highest cortisol level of the day, Adam and colleagues speculate that over time high levels contribute to changes in brain glucocorticoid receptors involved in the negative feedback regulation of the HPA axis, including changes in the hippocampus and amygdala and their dysfunctional effects in the cortical–limbic circuits underlying emotion regulation. As to the origins of elevated CAR, these authors note the possibility of genetically transmitted characteristics, but emphasize the likelihood that adverse experiences in childhood modify the developing brain and its HPA axis characteristics.

Genetics

There have been enormous empirical and methodological advances in genetic research in recent years, and these offer a wide array of approaches to the study of genetic contributions to psychological disorders. Depression, while one of the most prevalent of all public health issues, unfortunately offers a substantially heterogeneous phenotype for study, varying in symptomatology, comorbidity, severity, age of onset, course, and impairment. The topic of child and adolescent depression contributes its own unique issues and questions: Do genetic features apply similarly to child, adolescent, and adult populations? How are we to characterize nature–nurture questions? What is the nature/mechanism of genetic effects on depression in youth?

It has been well established in reviews and meta-analyses that depression runs in families (e.g., Rice, Harold, & Thapar, 2002), but the contributions of heritability and environment are obviously confounded, due to the psychological and environmental effects of depression and its vulnerabilities and risk factors for other family members. Quantitative genetic analyses in the form of twin studies provide methods of partitioning the variance contributed by genetic and environmental factors. In general, studies of adults report heritability estimates of around .4, with more variance accounted for by environmental factors, particularly that which is unique to individuals and not "shared" in family contexts (reviewed in Lau & Eley, 2010). When applied to children and adolescents, however, twin studies have provided more variable heritability estimates. Rice (2010) notes that heritability is nonsignificant in childhood samples (with high rates of environmental contribution), whereas heritability is significant among adolescents, similar to rates found in adult depression. The majority of twin studies of children and adolescents have been based on symptom measures of depression, with some differences depending on whether self-ratings or parental ratings are employed. Thus caution is warranted until further studies with more diagnostic-based ascertainment are conducted. The finding that adolescent but not childhood depression has a significant heritable component is consistent with several follow-up studies of depressed child patients into adulthood, which found relatively low rates of continuity of depression (although those who were not depressed as adults nonetheless had severe behavioral disorders and impaired functioning; see, e.g., Harrington et al., 1990; Weissman, Wolk, Wickramaratne, et al., 1999). It should be noted that although questions remain about heritability of depression across different ages, analyses of gender differences tend to find little evidence of different genetic contributions to males and females, despite the greater incidence of depressive disorders in females arising in adolescence (Franic, Middledorp, Dolan, Ligthart, & Boomsma, 2010).

Important developmental information has emerged from *longitudinal* twin studies. For example, Lau and Eley (2006) examined depressive experiences three times during adolescence and early adulthood in the G1219 study, finding evidence of "new" genetic and nonshared environmental influences emerging over time. The investigators speculated that such changes might contribute to the increasing rates of depression in adolescence, and that such changes might mutually influence each other (such as increasing selection into stressful situations, which themselves could trigger other genetically driven vulnerabilities toward depression). A longitudinal study of Swedish twins at four points between ages 8 and 20 by Kendler, Gardner, and Lichtenstein (2008) examined changes in genetic and environmental risk factors for mixed depression/anxiety symptoms. They found evidence for changes in genetic influences, with new influences coming "online," but also for attenuation of earlier influences on later symptoms. They conclude that genetic factors show a dynamic course over development, possibly contributing to the low continuity of symptoms from childhood to adolescence.

Although classical quantitative genetic analyses of twin samples permit the partition of variance in depression into genetic and environmental factors, newer methodologies have also yielded important leads. For example, the Children of Twins study of twin sets of parents and their children permits analysis of genetic effects separate from family (environmental) condi-

tions. Investigators Silberg, Maes, and Eaves (2010) examined whether genetic or family environmental factors (or both) provided the best explanation for the association between parent and offspring depression. The authors concluded that the best predictor of the associations between parent and offspring depression was family environment, whereas offspring conduct disorder was predicted by both genetic and environmental factors.

Research in psychopathology in general has increasingly developed techniques and devoted resources to the molecular genetic approaches to gene finding, including various studies of depression in adults. However, such strategies have not been applied to depressed child and adolescent samples, and probably need to be deferred until clearer resolution of age and developmental issues is attained. Nevertheless, there has been considerable interest in addressing the question of how genetic factors exert their effects—in both adult and child/adolescent depression—with increasing focus on candidate genes. Specifically, studies of gene–environment interactions (G×E), and to a lesser degree gene–environment correlations (*r*GE), have employed the same candidate genes as those studied in adult depression. It appears that, as in adults, depression in youth is associated with genetic risk for increased exposure to adverse environments (*r*GE) as well as greater reactivity to such environments (G×E). Notably, a polymorphism in 5-HTTLPR has been associated with adult depression, particularly under stressful conditions (reviewed in Karg, Burmeister, Shedden, & Sen, 2011). Several studies have found similar relevant patterns in depressed or "at risk" (due to maternal depression) children (e.g., Gibb, Uhrlass, Grassia, Benas, & McGeary, 2009; Hayden et al., 2008), and adolescent or mixed child/adolescent samples (Eley et al., 2004; Goodyer, Croudace, Dudbridge, Ban, & Herbert, 2010; see also Hankin, Jenness, Abela, & Smolen, 2011, for a longitudinal analysis). Other studies of candidate genes in adult depressed samples also have yielded evidence of gene–environment interactions (e.g., BDNF—Goodyer et al., 2010; Kaufman et al., 2006; dopamine D2 receptor gene—Hayden et al., 2010). Increasingly, investigators are integrating brain circuit activation with genetic analyses in youth samples. For example, as noted in the review of brain reactivity, Lau and colleagues (2010) found that adolescent depressed or anxiety patients who were BDNF Met carriers showed greater amygdala and hippocampal activations than those with Val/Val homozygotes, although many inconsistencies in findings across neuroimaging (and candidate gene–environment) studies are evident, suggesting needs for replication, larger and better-characterized or homogeneous samples, and measurement precision.

Studies of *r*GE are particularly needed for understanding risk for depression due to parental depression, as depression is strongly correlated with various environmental circumstances, such that children "inherit" not only genes but environments including dysfunctional parenting (a possible case of "passive" *r*GE). Evocative and active *r*GE may also occur, as when a child's heritable traits lead to behaviors that provoke reactions in others, which in turn contribute to depression (e.g., dependency may provoke rejection), or lead to selection into adverse environmental conditions (e.g., low self-esteem may contribute to the selection of dysfunctional romantic partners). *r*GE with respect to the occurrence of stressful life events is well known; Hammen (1991), for example, used the phrase "stress generation" to refer to the tendency of individuals with a history of depression (not just current depression) to contribute to the occurrence of stressful life events—a trend also observed in children with depression and children of depressed women. Starr, Hammen, Brennan, and Najman (2012) found that the presence of short alleles of 5-HTTLPR interacted with depression to predict stressful life events in a high-risk sample of adolescents. Lau and Eley (2008) applied quantitative genetic analyses to twins and siblings in the G1219 longitudinal study to test for different effects of *r*GE and G×E; they incorporated two measures of the environment—negative life events that had been at least partly caused by a participant, and participants' reports of maternal punitive discipline. The complex findings implicated both G×E and *r*GE on the two measures, and suggested that adolescent depression's genetic risks are due in part to exposure to these two adverse conditions, and that the adverse conditions themselves may activate genetic effects and increase the probability of depressive reactions. The authors call for further studies of the mechanisms by which genetic effects are mediated, including brain circuits such as amygdala reactivity, as well as cognitive and personality processes.

Although the future of genetic approaches to understanding depression in adults and youth will doubtless lead in exciting directions with the expansion and further development of traditional quantitative and molecular paradigms, *epigenetic* processes that determine the where, when, and how much of fundamental protein components of DNA will also increasingly expand our understanding of genetic mechanisms of behavior. As reviewed by Lau and Eley (2010), animal research on

how gene expression is affected by environmental experiences, such as maternal care, will invariably open up new findings and questions about the origins, developmental course, and stability of behavioral and emotional outcomes relevant to depression.

Summary

Undeniably, the past decade has seen a surge in interest and methodological advances in the study of biological characteristics associated with adult depression—and, by extension, child and adolescent depression. Considerable interest focuses on emerging evidence in depressed children and adolescents on dysfunctional neural circuits underlying emotional processing and their associations with brain regions and mechanisms of information processing and cognitive control, as well as the effects of dysregulated biological stress processes in the HPA axis, and their associations with neurocognitive mechanisms. Similarly, research has underscored the importance of genetically mediated influences. However, major questions remain about the origins and mechanisms of neural abnormalities, and the transactions among experiential and biological factors. Developmentally sensitive models, studied in longitudinal designs, are needed for the field to advance in the clarity of our understanding of depression as it appears in youth.

Emotional Vulnerability to Depression

Mood disruptions are fundamental to depression; consequently, developmental theory and research have sought to uncover the unique pathways through which emotional functioning contributes to risk for depression in youth. In addition to the biological and cognitive processes related to emotions reviewed in other sections of this chapter, investigations of emotional vulnerability to depression have explored stable, trait-like aspects of emotionality (i.e., temperament), and situational, state-like aspects of emotional processing, responses, and regulation.

Theoretical Models

One group of theoretical perspectives focuses on temperament, as reflected in stable individual differences in self-regulation and affect that are presumed to result from the interplay between biology and experience (Rothbart & Posner, 2006). Theorists have highlighted three dimensions of temperament with relevance to depression (for a review, see Rothbart & Posner, 2006): high negative emotionality (NE; a tendency toward experiencing frequent, intense, and lasting negative affect); low positive emotionality (PE; a tendency toward experiencing low levels of positive emotions such as joy and pleasure); and poor effortful control (EC; difficulty inhibiting undesired impulses and effectively regulating attention). According to the tripartite model, the combination of high NE and low PE differentiates depression from internalizing disorders such as anxiety (Clark & Watson, 1991). Together, NE, PE, and EC account for children's' dispositional emotionality and responsivity to emotionally evocative stimuli.

Theorists typically conceptualize temperament as a diathesis for depression (e.g., Hyde, Mezulis, & Abramson, 2008; Yap, Allen, & Sheeber, 2007). According to these models, temperament may serve as a vulnerability to depression directly, by fostering symptoms (e.g., depressed mood, anhedonia, irritability), or indirectly, by fostering emotional vulnerability (e.g., rumination, emotion dysregulation) or eliciting negative experiences (e.g., stress) that in turn contribute to depression. Temperament also may act as a moderator, shaping children's emotional reactivity to environmental risks for depression, consistent with broader developmental theories such as the biological sensitivity to context model (Boyce & Ellis, 2005). Importantly, these theoretical models predict that direct, indirect, and moderated pathways are complementary rather than mutually exclusive.

Other perspectives focus on individual differences in emotional responses, emotion regulation, and emotion processing as precursors to depression. Response style theory posits that individuals who tend to engage in unproductive emotion-related rumination sustain and amplify negative moods rather than resolve them, such that a ruminative response style contributes to the onset and maintenance of depression (for a review, see Rood, Roelefs, Bogels, Nolen-Hoeksema, & Schouten, 2009). Emotion regulation perspectives propose that a failure to effectively regulate emotional responses is fundamental to mood disorders including depression, and that poor emotion regulation early in development will set the stage for later symptoms (e.g., Compas, Jaser, & Benson, 2009). Building on emotion regulation perspectives, others have proposed that deficits in processing emotions (e.g., identifying and understanding emotions, regulating attention to emotions) may underlie emotion regulation difficulties, which in turn

are expected to heighten vulnerability to depression (e.g., Flynn & Rudolph, in press). Some aspects of executive functioning with relevance to emotion regulation, such as problem solving, response selection, and regulation of attention, could also play a role in shaping vulnerability to depression (e.g., McClintock, Husain, Greer, & Cullum, 2010), although research is needed in youth populations (see later discussion of cognitive vulnerabilities to depression). In recent years, emotion processing and regulation perspectives have increasingly focused on ways that developmental changes in emotional functioning, particularly related to biological maturation (e.g., puberty, neurological maturation), may contribute to the higher prevalence of depressive symptoms in adolescence (e.g., Forbes, Phillips, Ryan, & Dahl, 2011).

Empirical Evidence

TEMPERAMENT

Empirical investigations of temperament and depression generally support theoretical predictions. Prospective research supports direct associations between high NE and depressive symptoms in adolescence (e.g., Krueger, 1999). Furthermore, heightened rumination (Mezulis, Simonson, McCauley, & Vander Stoep, 2011) and generation of stressful life events (Barrocas & Hankin, 2011) mediate the prospective association between NE and depression in youth; emotion dysregulation mediates the prospective link between EC and depression (Zalewski, Lengua, Wilson, Trancik, & Bazinet, 2011). Temperament also moderates the impact of environmental factors on depression. In some cases, temperamental vulnerability (e.g., high NE, low EC) enhances the contribution of environmental factors—such as negative parenting (Kiff, Lengua, & Bush, 2011) and peer victimization (Sugimura & Rudolph, 2012)—to depression. However, temperament also may promote resilience; for example, Gartstein and Bateman (2008) found that low NE attenuated the link between maternal depression in infancy and depression-like symptoms in toddlerhood.

EMOTION PROCESSING

A number of emotion-processing deficits are associated with vulnerability to depression in youth. Depressive symptoms are correlated with youth's inaccurate identification of parents' emotions in parent–child interactions (Ehrmantrout, Allen, Leve, Davis, & Sheeber, 2011) and with perceptions of more anger and less joy in low-intensity facial stimuli (van Beek & Dubas, 2008). Regarding one's own emotions, low emotional clarity, or difficulty identifying and distinguishing between one's emotions, and perceptual asymmetry in processing of emotional faces (i.e., reduced posterior right-hemispheric bias) predict subsequent depressive symptoms in youth. Importantly, maladaptive responses to stress (e.g., low levels of engagement strategies, such as emotion regulation; high levels of dysregulated, automatic responses, such as rumination and emotional numbing) mediated these associations, supporting the idea that poor emotion regulation is a mechanism through which emotion-processing deficits increase vulnerability to depression (Flynn & Rudolph, 2010a, 2010b, in press).

EMOTION REGULATION

Depressed youth also exhibit compromised emotional responses and regulation. Depressive symptoms are correlated with parent and self-reports of poor emotion regulation (for a review, see Durbin & Shafir, 2008). Corroborating these findings, cross-sectional research indicates that compared to nondepressed youth, depressed youth exhibit more dysregulated expressions of negative affect as indexed by experience-sampling methods (Silk et al., 2011) and observations (Sheeber et al., 2009). Some longitudinal research supports the idea that poor emotional functioning sets the stage for later depression in youth. Consistent with response style theory, emotion-related rumination is a robust prospective predictor of heightened depressive symptoms, particularly among adolescents (for a meta-analysis, see Rood et al., 2009). Limited research reveals prospective links between aspects of poor emotion regulation and youth depression, including high emotional inertia (i.e., temporally persistent moods; Kuppens et al., 2011) and poor regulation of sadness and anger (Feng et al., 2009).

Origins and Development of Emotional Vulnerability

Both environmental and biological factors play a role in shaping the development of emotional vulnerability to depression in youth. Considerable evidence links early adversity (e.g., maltreatment, parent depression) to disruptions in emotional processing and regulation (at both biological and behavioral levels) among youth consid-

ered at risk for depression (for a review, see Abaied & Rudolph, 2014). Proximal environmental factors, such as maladaptive parent socialization of emotion regulation and coping, also contribute to deficits in emotional functioning and depression (e.g., Abaied & Rudolph, 2010b, 2011). However, additional research is needed to test directly whether youth emotional functioning accounts for prospective contributions of adversity and parent socialization to depression.

Developmental neuroscience research suggests that emotional vulnerability to depression also has neurological underpinnings. Researchers have proposed that reduced neural response to rewards may underlie the low levels of PE common to depression, and that biological maturation may exaggerate this pattern in adolescence (for a review, see Forbes & Dahl, 2012). Youth at risk for depression (e.g., daughters of depressed mothers) also show maladaptive patterns of neural activity during emotion regulation tasks (e.g., Joormann et al., 2012). These processes may be affected by endocrinological changes associated with pubertal maturation; Forbes and colleagues (2011) found that pubertal maturation rather than age predicted less activation in brain regions associated with emotion regulation in response to social threats. Outside the context of neuroscience research, Silk and colleagues (2011) found that depressed adolescents experienced higher levels of negative emotions than nondepressed adolescents, and that this difference was amplified among those with advanced pubertal status. These puberty-related changes in emotional vulnerability may help to explain the higher rates of depression onset in adolescence than in childhood.

Summary

Emotional vulnerability to depression operates though both state- and trait-like processes. Prospective designs provide ample empirical support for temperament models of depression and response style theory, such that youth's dispositional emotionality and style of emotional responses are implicated in the development of depression. Although research supports emotion processing and regulation deficits among depressed youth and youth at risk for depression (i.e., those exposed to early adversity), additional longitudinal investigations are needed to more clearly differentiate emotion regulation deficits as antecedents versus consequences of depression. Future research also should seek to elucidate the pathways though which multiple levels of emotional functioning (i.e., biological, cognitive, behavioral) combine and interact to shape vulnerability to depression.

Cognitive Vulnerability to Depression

Cognitive models implicate negative belief systems and maladaptive information processing in the onset and course of depression. According to these models, cognitive vulnerability serves as a stable predisposition that interacts with life stress to predict depression. This vulnerability is reflected in characteristic biases in attention, interpretation, and recall of information. More specifically, cognitive theories often suggest that a key determinant of depression is the *match* between a particular cognitive vulnerability and a particular stressor. That is, stressful events or circumstances would induce depression to the extent that they precipitate a loss of self-worth in an individual's specific area of cognitive vulnerability. In this regard, the most common distinction focuses on individual differences in the tendency to base one's self-worth either on success in interpersonal relationships (as reflected in sociotropy or dependency) or on individual achievement and independence (as reflected in autonomy or self-criticism) (Beck, 1987; Blatt & Zuroff, 1992; Coyne & Wiffen, 1995).

Theoretical Models

Beck's (1967, 1987) cognitive theory of depression elucidates three aspects of disrupted cognitive functioning in depression. First, depressed individuals possess core dysfunctional attitudes and negative cognitive schemas (characterized by themes of loss, failure, and inadequacy) that guide information processing. Second, these schemas drive systematic biases in thinking, which create idiosyncratic interpretations of events (e.g., negative automatic thoughts, cognitive errors). Third, depression is associated with the "negative cognitive triad," or a tendency to possess negative views of the self as worthless or inadequate, the world as mean or unfair, and the future as hopeless. The theory maintains that these cognitive styles heighten susceptibility to depression, especially when activated by external stressors. Because the rigid nature of cognitive schemas renders them highly resistant to change, depressed individuals may be vulnerable to persistent difficulties.

A second set of cognitive theories involves reformulations of Seligman's (1975) "learned helplessness" model. The original version posited that depression

stems from the experience of uncontrollable, noncontingent events. A revision of this model (Abramson, Seligman, & Teasdale, 1978) introduced the notion of a "depressive attributional style," or a predisposition to attribute negative outcomes to internal, global, and stable factors, and positive outcomes to external, specific, and unstable factors. In the most recent version of this model, Abramson, Metalsky, and Alloy (1989) described a subtype of "hopelessness" depression, which evolves from the interaction between exposure to negative events and a depressogenic inferential style involving pessimistic inferences about the causes, consequences, and self-implications of events.

Related self-regulatory theories (Rehm, 1977; Weisz, Sweeney, Proffitt, & Carr, 1994) suggest that one's expectations about outcomes (e.g., perceptions of control and competence, outcome contingencies) and one's personal investment in outcomes (e.g., goals, standards, values) jointly confer vulnerability to depression. Competence-based models focus in particular on the perceived competence aspect of self-regulation (Cole, Martin, & Powers, 1997). Appraisal-based models emphasize maladaptive appraisals about the meaning of events (a tendency to appraise challenging events as threatening, harmful, or stressful, rather than as opportunities for learning, mastery, and growth; Lazarus & Folkman, 1984).

Response style theory (Nolen-Hoeksema, 1991) proposes that depression arises from individual differences in self-focused attention. According to this theory, the tendency to "ruminate"—rather than distract oneself—in response to negative affect determines susceptibility to persistent and severe depression. Rumination involves perseverating on depressive symptoms and the possible causes and consequences of symptoms. More recent elaborations of this theory distinguish two dimensions of rumination (Treynor, Gonzalez, & Nolen-Hoeksema, 2003). Whereas "brooding" involves passively focusing on symptoms, "self-reflection" involves actively attempting to gain insight into one's problems. It is thought that brooding, but not self-reflection, serves as a specific vulnerability for depression.

Empirical Evidence

Over the past decade, researchers have increasingly used prospective designs to evaluate the etiological significance of cognitive vulnerability, as well as to test cognitive vulnerability–stress interactions. This research has yielded significant support for cognitive vulnerability–stress models of depression in youth, although there are exceptions, with some studies yielding qualified support (e.g., by age, type of outcome, interactions with other vulnerabilities) or no support for these models (for reviews, see Abela & Hankin, 2008; Gibb & Coles, 2005; Jacobs, Reinecke, Gollan, & Kane, 2008).

SELF-REPORTED BELIEFS AND STYLES

Most longitudinal research uses self-report questionnaires to examine explicit aspects of cognitive vulnerability, such as dysfunctional attitudes (e.g., perfectionism, need for social approval), negative automatic thoughts (e.g., catastrophization, overgeneralization), negative inferential style (e.g., stable, global attributions for failure), self-critical thoughts, low perceived control, and ruminative response styles. Overall, this research provides compelling evidence for the idea that self-reported cognitive vulnerability alone and, in particular, vulnerability–stress interactions prospectively contribute to subsequent depressive symptoms and disorders in youth.

Examining Beck's theory, a few studies provide partial or full support for the idea that dysfunctional attitudes prospectively interact with stress to predict depressive symptoms (e.g., Abela & Skitch, 2007; Hankin, Abramson, Miller, & Haeffel, 2004; Lewinsohn, Joiner, & Rhode, 2001). Examining the hopelessness theory, a growing number of studies reveal that depressive attributions about the causes of events interact with stress to predict depressive symptoms (e.g., Abela et al., 2011; Bohon, Stice, Burton, Fudell, & Nolen-Hoeksema, 2008; Carter & Garber, 2011; Hankin, 2008). A few studies provide partial or full support for the predictive contribution of depressogenic inferences about the consequences and self-implications of events (e.g., Abela, 2001, 2002). Building on these findings, Abela and colleagues (e.g., Abela & Sarin, 2002) have shown that it may be important to identify youth's "weakest link"—namely, their most negative cognitive style—in research examining cognitive vulnerability–stress interactions. Research also supports the predictive contribution of perceived competence (Tram & Cole, 2000) and control (Rudolph, Kurlakowsky, & Conley, 2001) to depressive symptoms. Finally, ruminative response style alone (Nolen-Hoeksema, Stice, Wade, & Bohon, 2007) and in interaction with stress (Abela & Hankin, 2011) predicts subsequent depression. When subtypes are distinguished, effects hold

for brooding rather than reflection; moreover, brooding accounts for stability in depressive symptoms in girls but not in boys (Burwell & Shirk, 2007). Despite evidence for cognitive vulnerability–stress models, it is noteworthy that some studies provide only partial or no support for these theories (for reviews, see Abela & Hankin 2008; Gibb & Coles, 2005; Jacobs et al., 2008); moreover, research often supports a reciprocal association wherein depressive symptoms predict subsequent maladaptive cognitions (e.g., LaGrange et al., 2011).

Less research has tested the validity of cognitive specificity models in youth. Some research supports self-criticism × achievement stress contributions (Abela, Sakellaropoulo, & Taxel, 2007) and dependency × interpersonal stress contributions (Little & Garber, 2000) to depressive symptoms over time; however, other research has not supported the predictive role of cognitive vulnerability–stress match (for a review, see Abela & Hankin, 2008). Research also reveals that depressogenic interpersonal beliefs and schemas (negative beliefs and biased processing about interpersonal relationships) confer vulnerability to depression in the face of interpersonal stress (Hammen et al., 1995; Shirk, Boergers, Eason, & Van Horn, 1998). These preliminary findings indicate the need for further pursuit of longitudinal research on domain-specific cognitive vulnerability and cognition–stressor match.

INFORMATION-PROCESSING BIASES

Researchers have used two approaches to examine the role of implicit information-processing biases in depression. The first approach involves experimental assessments of selective attention and memory. Relative to nondepressed youth, depressed youth show an attentional bias toward sad faces (Hankin, Gibb, Abela, & Flory, 2010) and idiosyncratic processing of self-referent (Hammen & Zupan, 1984; Neshat-Doost, Taghavi, Moradi, Yule, & Dalgleish, 1998) and other-referent (Rudolph, Hammen, & Burge, 1997) information. This research reveals that depressed youth show either more of a bias toward negative stimuli, or less of a bias toward positive stimuli, than do nondepressed youth, although there are exceptions (for a review, see Jacobs et al., 2008).

The second approach involves examining the accuracy of cognitive appraisals in depressed youth. Most investigations of cognitive vulnerability assess decontextualized belief systems (e.g., generalized dysfunctional attitudes) or interpretations of hypothetical events (e.g., negative inferential style), making it difficult to determine the accuracy of depressogenic cognitive styles. Although we might surmise that extreme negative beliefs (e.g., catastrophization) are at least somewhat biased, it is clear that depressed youth do, in fact, experience significant competence deficits and environmental adversity (for a review, see Rudolph, Hammen, & Daley, 2006). Thus characteristic negative cognitions could, at least in part, reflect realistic appraisals of such disturbances. To resolve this issue, a few studies have examined the accuracy of appraisals by assessing cognitions within the context of actual life experiences.

Examining self-appraisals of competence, research reveals that depressed youth underestimate their competence relative to objective ratings (e.g., Brendgen, Vitaro, Turgeon, & Poulin, 2002), supporting the presence of a depressive bias in self-appraisal. Examining appraisals of naturally occurring life events, one study confirms that depressed youth overestimate event stressfulness (the degree of negative impact associated with events) and event dependence (the extent to which the youth contributed to event occurrence) relative to objective ratings (Krackow & Rudolph, 2008), confirming the presence of a depressive bias in appraisals of event meaning, causes, and consequences.

Despite evidence for information-processing biases in depressed youth, this research is limited by several methodological constraints. First, studies of information processing primarily use concurrent designs, precluding strong conclusions regarding the temporal precedence of cognitive vulnerability. Indeed, a few studies (Cole, Martin, Peeke, Seroczynski, & Hoffman, 1998; McGrath & Repetti, 2002; Pomerantz & Rudolph, 2003) suggest that depressive symptoms foster biased self-appraisals (i.e., underestimations of competence) over time. Second, research reveals that depressed youth are sensitive to actual deficits in their competence (Rudolph & Clark, 2001), suggesting some realistic basis for negative appraisals and the need for future research to distinguish realistic versus distorted perceptions of reality. Third, much of this research overlooks the contextual component of cognitive theories—namely, that depressogenic cognitive schemas may remain latent until activated by negative mood states or events. To address this concern, future research needs to assess information-processing biases under conditions of cognitive activation, such as following negative mood induction (e.g., Taylor & Ingram, 1999), or as a diathesis that interacts with stressful life events to predict depression.

Origins and Development of Cognitive Vulnerability

For a full understanding of the role cognitive vulnerability plays in depression, it is important to elucidate how it emerges and develops over time. Original cognitive theories, developed in adults, view cognitive vulnerability as an early-emerging and persistent predisposition stemming from adverse experiences. This perspective assumes that cognitive vulnerability is a relatively stable, latent personality trait that is activated by mood-related or environmental triggers (Joormann, 2009). Prompted by research suggesting developmental differences in the stability and predictive validity of cognitive vulnerability (for a review, see Abela & Hankin, 2008), as well as research suggesting that depressive symptoms may leave a cognitive "scar" (Nolen-Hoeksema, Girgus, & Seligman, 1992; Pomerantz & Rudolph, 2003), the field of developmental psychopathology increasingly views cognitive vulnerability as a dynamic construct that crystallizes over the course of development, perhaps in response to maturational and experiential changes during the transition through adolescence.

INDIVIDUAL-DIFFERENCE ORIGINS

There is some evidence for a genetic liability to cognitive vulnerability, including negative attributional style (Lau, Rijsdijk, & Eley, 2006), information-processing biases (Beevers, Wells, Ellis, & McGeary, 2009; Pérez-Edgar et al., 2010) and rumination (Beevers, Wells, & McGeary, 2009). Research also has investigated the neural and biological basis of cognitive vulnerability. For example, differential patterns of brain activation (Monk et al., 2008) and heightened cortisol activation to stress (Rudolph, Troop-Gordon, & Granger, 2011) are linked to attentional biases and rumination, respectively. Temperament or personality traits may play a role in the development of cognitive vulnerability. One study revealed that low levels of positive emotionality in early childhood predicted subsequent information-processing biases (less recall of positive self-referent information; Hayden, Klein, Durbin, & Olino, 2006). Another study revealed that depressive personality traits were associated with girls' tendency to overestimate the stressfulness of events and their contribution to events, even after the researchers adjusted for lifetime history of depression (Rudolph & Klein, 2009). Increasing interest also has emerged in how core executive functions (cognitive processes that guide planning, decision making, and self-regulation) influence cognitive vulnerability to depression. For example, deficits in cognitive inhibition interfere with efficient updating of working memory (i.e., focusing attention on relevant information and ignoring irrelevant information), setting the stage for rumination, information-processing biases (e.g., elaboration of and difficulty disengaging from negative material), and other forms of cognitive vulnerability (for reviews, see Gotlib & Joormann, 2010; Joormann, 2009). Given these links, it is not surprising that executive function deficits are associated with depression in adults (for a review, see Gotlib & Joormann, 2010); research with youth is more limited and typically relies on adult reports of temperamental dimensions associated with executive functions, such as EC and attention regulation, rather than cognitive tasks (for a review, see Eisenberg, Smith, Sadovsky, & Spinrad, 2004).

SOCIAL-CONTEXTUAL ORIGINS

Several theories suggest that early exposure to chronic or severe adversity (e.g., trauma, family disruption, life stressors, maladaptive parent socialization) is internalized in the form of cognitive vulnerability (e.g., Gibb & Coles, 2005; Rose & Abramson, 1992). Consistent with this idea, mounting evidence reveals that such forms of adversity predict the emergence of cognitive vulnerability over time in youth (for reviews, see Abela & Hankin, 2008; Gibb & Coles, 2005). Research also documents information-processing biases in the offspring of depressed mothers. In one study, never-disordered daughters of depressed mothers selectively attended to negative emotional information, while never-disordered daughters of never-disordered mothers selectively attended to positive emotional information (Joormann, Talbot, & Gotlib, 2007). In another study, maternal depressive symptoms were associated with a negative bias in youth's processing of mother-relevant information (specifically for youth with heightened emotional reactivity to stress; Flynn & Rudolph, 2012). Offspring of mothers with a history of depression also show patterns of psychophysiological functioning suggestive of deficits in selective attention (Pérez-Edgar, Fox, Cohn, & Kovacs, 2006). Collectively, these studies support the idea that stressful life contexts foster the development of cognitive vulnerability, which may contribute to the intergenerational transmission of depression. Of course, it also is possible that childhood adversity and maternal depression reflect a genetic liability that is in-

stantiated in the form of cognitive vulnerability. Additional research is needed to determine the mechanisms through which adverse contexts and maternal depression heighten cognitive vulnerability.

DEVELOPMENTAL CHANGES

A quantitative review (Lakdawalla, Hankin, & Mermelstein, 2007) reveals that the cognitive vulnerability–depression link strengthens with age; this finding indicates the importance of understanding changes in the stability, consolidation, and predictive power of cognitive vulnerability across development. Several cognitive transformations during the adolescent transition may set the stage for increasing cognitive vulnerability (for reviews, see Abela & Hankin, 2008; Gibb & Coles, 2005; Jacobs et al., 2008). Cognitive vulnerability may emerge as children develop the capacity to engage in abstract reasoning, integrate information across situations and time, and make stable attributions about behavior. Cognitive processes also become more rigid across development, making it less likely that individuals will flexibly integrate schema-incongruent information; this rigidity may be intensified by normative increases in self-consciousness during adolescence. At the same time, a maturational gap emerges between emotional reactivity and cognitive regulatory capacity (Dahl, 2004), laying fertile ground for the cultivation of emotionally driven difficulties in regulatory focus (e.g., rumination) and unchecked negative inferences about stressful events. These maturational changes may intersect with increasing life stress during adolescence (Rudolph & Hammen, 1999) to set the stage for heightened cognitive vulnerability. Shifts also may occur in the association between cognitive vulnerability and stressors. Whereas cognitive vulnerability may emerge from stressors (Tram & Cole, 2000) or prior depressive symptoms (LaGrange et al., 2011; Pomerantz & Rudolph, 2003) earlier in development, it may interact with stressors later in development. Moreover, cognitive vulnerability contributes to the generation of stress (e.g., Eberhart, Auerbach, Bigda-Peyton, & Abela, 2011; Shih, Abela, & Starrs, 2009), highlighting the dynamic association between cognitions and stress.

Given evidence for distinct dimensions of cognitive vulnerability in youth (Ginsburg et al., 2009), it is possible that these dimensions coalesce into stable traits at different stages of development. Supporting this idea, research using an advanced quantitative modeling approach suggests that a reliable time-invariant (trait-like) component of negative attributional style does not emerge until early adolescence (Cole et al., 2008), whereas stable components of other negative cognitions (negative automatic thoughts, the negative cognitive triad) emerge during middle childhood (LaGrange et al., 2011). These findings underscore the need to distinguish various aspects of cognitive vulnerability, some of which may be more accessible and well developed earlier in childhood (and thus serve as predictors of depression), and others of which may involve more complex cognitive processes (e.g., making inferences about events) and do not stabilize until youth show certain cognitive advances during adolescence. Once the various components reach a certain level of stability (i.e., become trait-like), they may consolidate into a single set of interrelated vulnerabilities (Abela & Hankin, 2008).

Summary

Early research often failed to test key aspects of cognitive vulnerability models, such as the temporal precedence and stability of dysfunctional cognitive styles, the activation of cognitive vulnerability by negative mood states or stressors, and the accuracy of negative cognitions. Notable advances in the use of rigorous, prospective, multiwave, and experimental designs over the past decade address many of these limitations. As a result, the field has witnessed significant progress in addressing some of the ongoing controversies and affirming the position of cognitive theories as useful conceptual frameworks for understanding the etiology and persistence of depression. At the same time, recent advances illustrate the need to embed cognitive theories of depression within the context of dynamic developmental frameworks that explain the emergence, consolidation, and crystallization of cognitive vulnerability over time. Future efforts to refine and validate cognitive theories of depression must elucidate the independent, transactional, and interactive contributions of cognitive vulnerability and other risk factors (e.g., genetic, biological, emotion-regulating, and social processes) with the goal of developing integrative multilevel models.

Interpersonal Vulnerability to Depression

Interpersonal approaches to understanding depression posit that depression is fundamentally an interpersonal disorder (Coyne, 1976; Joiner & Timmons, 2009). Interpersonal difficulties are robust predictors and consequences of depression, and many other forms of vulnerability to depression (e.g., cognitive, emotional)

are expressed in interpersonal contexts. Furthermore, interpersonal vulnerability to depression may be of particular import for youth, whose relationships evolve dramatically over the course of childhood and adolescence. In recent years, substantial progress has been made in theory and research seeking to understand interpersonal vulnerability to depression in youth.

Theoretical Models

According to interpersonal theories of depression, originally developed to understand adult depression, depressed individuals both *react* and *contribute* to interpersonal difficulties. Specifically, impairment in social skills (e.g., excessive reassurance seeking, social withdrawal) and relationship disturbances (e.g., unsupportive or conflictual relationships, interpersonal stress) heighten vulnerability to depression. In turn, characteristics and behaviors of depressed individuals contribute to stress in relationships, aversive interpersonal encounters, and rejection, which maintain or promote depression over time (Coyne, 1976; Gotlib & Hammen, 1992; Joiner & Timmons, 2009). This cyclical process may help to explain high stability and recurrence of depression.

Extensions of these theories to youth provide developmentally sensitive accounts of the early origins of interpersonal disruption, as well as the continuously evolving interplay between interpersonal disruption and depression over time and across critical developmental stages (e.g., Cyranowski et al., 2000; Rudolph, Flynn, & Abaied, 2008). According to these models, early exposure to social adversity may set the stage for proximal interpersonal vulnerabilities in youth. These models take into account key developmental transitions, paying particular attention to ways in which biological (e.g., puberty, sex), cognitive (e.g., executive functioning, abstract reasoning), and social (e.g., increasing importance of peers and romance) development may exacerbate preexisting interpersonal vulnerability and contribute to the sharp increase in depression beginning in midadolescence. Finally, developmental perspectives on the interpersonal context of depression posit that interpersonal vulnerabilities may manifest themselves in a variety of relationship contexts, including family, peer, and romantic relationships.

Empirical Evidence

Longitudinal research supports both directions of influence—interpersonal impairments and problems predicting youth depression, and youth depression predicting incompetence and dysfunction in relationships—in multiple interpersonal domains. We first discuss research covering interpersonal stress across different domains and then focus on specific relationships, including those with family, peers, and romantic partners, focusing on links between proximal aspects of youth's relationships and depression.

INTERPERSONAL STRESS

Exposure to interpersonal stressors (pooled across multiple types of relationships) predicts subsequent depression in youth (e.g., Carter & Garber, 2011; Hankin, Mermelstein, & Roesch, 2007). Furthermore, the process of interpersonal stress generation, in which depressive characteristics and behaviors (e.g., excessive reassurance seeking, negative conceptions of relationships) disrupt relationships and create new interpersonal stressors, also contributes to the maintenance of depression over time (for a review, see Hammen, 2009a). Consistent with the idea that depression is particularly damaging to relationships, depressed youth are more likely to generate interpersonal than noninterpersonal stress (Hammen, 2009a; Rudolph, Flynn, Abaied, Groot, & Thompson, 2009).

FAMILY RELATIONSHIPS

Drawing from family systems (Cox & Paley, 1997) and attachment theory (Bowlby, 1969) perspectives, much of the research on interpersonal vulnerability to depression in youth focuses on the family context. Youth who are exposed to stressful and unsupportive family environments and maladaptive parenting are at heightened risk for developing depression. Families of depressed youth are more conflictual and less cohesive compared to families of nondepressed youth, and parents of depressed youth are more negative (i.e., unsupportive, hostile, or intrusive) in parent–child interactions compared to parents of nondepressed youth (for a review, see Abaied & Rudolph, 2014). Aspects of the family environment (e.g., high parent–child conflict, coercive and emotionally negative interactions among family members) and parenting behavior (e.g., low parental warmth, parent hostility, and psychological control) forecast subsequent depression in youth (e.g., Schwartz et al., 2011; Soenens et al., 2008; Stice, Ragan, & Randall, 2004), and a highly critical parenting style predicts the onset (Silk et al., 2009) and maintenance (McCleary & Sanford, 2002) of youth depression.

As predicted by interpersonal theories of depression, youth depressive symptoms also disrupt family environments. Youth depression predicts more stress in parent–child relationships (Raposa, Hammen, & Brennan, 2011), lower perceived family relationship quality (Lewinsohn, Rohde, et al., 2003), and lower perceived support from parents (Needham, 2007) over time. Furthermore, depressed youth perceive their parents as increasingly hostile, harsh, and inconsistent over time (Kim, Conger, Elder, & Lorenz, 2003). Observational research has revealed more negative interchanges, less positive reciprocity, and more negative reciprocity between depressed children and their parents than in nondepressed families (for a review, see Abaied & Rudolph, 2014). Thus depressed children's symptoms or dysfunctional behavior may evoke negative responses from their parents and perpetuate negative parent–child interactions over time. Providing some support for transactional associations, some research documents reciprocal effects between low perceived parent support and depressive symptoms (Allen et al., 2006; Branje, Hale, Frijns, & Meeus, 2010; cf. Stice et al., 2004). Therefore, substantial evidence supports problematic family relationships as both predictors and outcomes of youth depression.

PEER RELATIONSHIPS

Learning to build and maintain positive relationships with peers, with whom most youth spend a large portion of their time, is a key developmental task in childhood, and peer relationships become more central to self-worth and emotional well-being during the transition to adolescence (Laursen, 1996). Thus, in recent years, researchers have paid increasing attention to peer relationships as a context of vulnerability to depression. Building on early cross-sectional work identifying a variety of impairments in depressed children's relationships with peers (e.g., Rudolph & Clark, 2001; for a review, see Gotlib & Hammen, 1992), investigators have demonstrated that deficits in interpersonal behaviors within peer relationships, including excessive reassurance seeking, negative feedback seeking, social withdrawal, and ineffective responses to peer stressors contribute to subsequent depression (e.g., Agoston & Rudolph, 2011; Borelli & Prinstein, 2006; Prinstein et al., 2005). Furthermore, exposure to social difficulties such as peer rejection, exclusion, victimization, and poor-quality friendships predict heightened depressive symptoms over time (Burton, Stice, & Seely, 2004; Nolan, Flynn, & Garber, 2003; Rudolph, Troop-Gordon, Hessel, & Schmidt, 2011). Supporting early (Coyne, 1976) and updated (Joiner & Timmons, 2009) interpersonal theories of depression, depressive symptoms also are contagious within peer groups, such that depressive symptoms in one's peers predict increases in one's own depression over time, with stronger effects generally emerging for girls compared to boys (e.g., Conway, Rancourt, Adelman, Burk, & Prinstein, 2011; van Zalk, Kerr, Branje, Stattin, & Meeus, 2010). One mechanism of depression contagion may be "co-rumination" (i.e., extensively discussing problems and negative feelings). Co-rumination among friends, although associated with higher friendship quality, predicts subsequent heightened depressive symptoms among girls (Rose, 2002; Rose, Carlson, & Waller, 2007). Together, these findings indicate that impaired functioning within peer relationships constitutes a substantial risk factor for subsequent depression.

Depression also interferes with children's subsequent interpersonal functioning. Depressed children have difficulty negotiating peer conflicts, and they elicit negative affect and aversive responses from unfamiliar peers (e.g., Rudolph, Hammen, & Burge, 1994), suggesting that characteristics of depressed children undermine the quality of their interactions. Perhaps as a result, children with the highest levels of depressive symptoms are most likely to lose friends over time (van Zalk et al., 2010), and depressive symptoms prospectively predict less stable and poorer-quality friendships (Oppenheimer & Hankin, 2011; Prinstein, Borelli, Cheah, Simon, & Aikins, 2005). Providing insight into two pathways through which depression can undermine peer relationships in youth, Agoston and Rudolph (2013) found that socially helpless behavior (e.g., lack of social initiative and persistence in the face of social challenge) and aggressive behavior accounted for the prospective contribution of depressive symptoms to low social status over time. In sum, disruptions in peer relationships may be antecedents or consequences of depression in youth.

ROMANTIC RELATIONSHIPS

Despite the developmentally salient and normative nature of adolescent romantic attraction and involvement (Collins, 2003), a small but growing literature suggests that romantic involvement in adolescence represents a substantial risk factor for subsequent depression (Davila et al., 2009; Starr, Davila, et al., 2012). Davila (2008) proposes that many youth lack the resources

to cope effectively with the challenges associated with romance, leaving romantically involved youth vulnerable to depression; for example, romance often involves intense and potentially novel emotions (e.g., sexual attraction, passion, romantic love) and introduces a variety of stressors (e.g., rejection, breakups, initiation of sexual behavior).

Consistent with this view, stress in romantic relationships (Daley & Hammen, 2002), negative interactions with partners (La Greca & Harrison, 2005), and low levels of intimacy (Williams, Connolly, & Segal, 2001) are associated with vulnerability to depression above and beyond involvement in romance. Romantic breakups constitute a particularly robust predictor of depressive symptoms and the onset of depressive episodes (Joyner & Udry, 2000). Supportive, low-conflict family relationships protect romantically involved youth from depression (Steinberg & Davila, 2008), whereas excessive reassurance seeking (Starr & Davila, 2008) and a preoccupied relational style (Davila, Steinberg, Kachadourian, Cobb, & Fincham, 2004) exacerbate this association. Thus lack of access to social support for coping with romantic stress may help to explain the link between romance and depression. Some studies have found stronger links between romantic involvement and depression or internalizing symptoms among girls compared to boys, and among younger compared to older adolescents (e.g., Joyner & Udry, 2000; Zimmer-Gembeck, Siebenbruner, & Collins, 2001).

Depression also may foster dysfunction in romantic relationships. In adolescence, depression is associated with generation of subsequent stress in romantic relationships (Hankin et al., 2007) and with dysfunction in romantic relationships, such as partner relationship dissatisfaction and physical coercion (Rao, Hammen, & Daley, 1999). Similarly, Daley and Hammen (2002) found that late adolescent women's depressive symptoms predicted lower levels of emotional support from their partners over time. Thus preliminary evidence supports disruption in romantic relationships as not only an antecedent but also a consequence of depression.

Summary

Supporting interpersonal theories of depression, research indicates that functioning within multiple domains of relationships may both contribute to and result from depression in youth. Relevant aspects of interpersonal functioning include dysfunctional social behaviors, poor-quality or unsupportive relationships, negative interactions with others, and interpersonal stress. Despite the transactional nature of interpersonal theories of depression, the majority of longitudinal studies in this area have focused on unidirectional pathways, and those that have tested transactional pathways have yielded inconsistent results; some only found support for one direction of effect or the other (Agoston & Rudolph, 2013; Borelli & Prinstein, 2006; Oppenheimer & Hankin, 2011; Prinstein et al., 2005; Stice et al., 2004). Unexamined moderators known to contribute to depression (e.g., genetic risk, cognitive style, or pubertal development) may have masked transactional effects in these studies. Future efforts to uncover transactional pathways should focus on moderators that are highly relevant to the aspects of interpersonal vulnerability being studied. In addition, most research in this area focuses on one relationship, and research is needed to examine the relative impact of different interpersonal contexts on depression in youth. Finally, long-term longitudinal studies will provide much-needed empirical tests of the core predictions stemming from developmental theories of interpersonal vulnerability to depression, including the notion that proximal interpersonal vulnerability is a mechanism through which early social adversity sets the stage for depression in childhood and adolescence.

Early Social Adversity and Depression

Moving beyond the proximal interpersonal context, developmental psychopathology theories of depression increasingly consider the adverse long-term consequences of early social adversity. Both prospective and retrospective research implicates early exposure to adverse social environments—through parental depression, trauma, loss, maltreatment, insecure attachment, or family disruption—as a precursor to youth depression (e.g., Garber & Cole, 2010; Hazel, Hammen, Brennan, & Najman, 2008; for a review, see Goodman & Brand, 2009). To achieve a better understanding of the relevant explanatory mechanisms, recent efforts have focused on articulating how early adversity undermines youth development in ways that heighten subsequent risk for depression.

Models of Risk

Developmental scientists have proposed several nonspecific models of early risk with potential relevance for youth depression. O'Connor (2003) distinguishes

three models accounting for the long-term impact of early experience. Most relevant to understanding the effects of early adversity on depression are the "experience-adaptive" or "developmental programming" model and the "cumulative-effects" model. An experience-adaptive model holds that biological systems adapt to environment input, particularly during sensitive periods of development; moreover, this malleability is developmentally constrained, such that systems have difficulty readjusting to later changes in the environment (although they may be altered through direct intervention). A cumulative-effects model holds that early experiences have a long-term impact to the extent that these effects are reinforced or maintained by later events; this model includes both an additive-effects variant (the effects of later adversity add to the effects of earlier risks) and an interactive-effects variant (the effects of later adversity depend on the history of earlier risks). Boyce and Ellis's (2005) "biological sensitivity to context" model combines elements of the experience-adaptive and cumulative-effects models; specifically, this model suggests that early adversity calibrates the stress response system, such that youth exposed to stressful early social environments show heightened biological reactivity to later stress. In something of a departure from other risk models, this sensitivity is thought to exert risk-augmenting effects under subsequent stressful conditions, but risk-protective effects under subsequent supportive conditions.

Focusing more specifically on interpersonal processes and depression, Rudolph and colleagues (2008) present an integrative model wherein early family adversity (e.g., insecure parent–child attachment, parental depression) interferes with the development of adaptive interpersonal behaviors and fosters maladaptive interpersonal behaviors. These social-behavioral deficits cause youth to generate further disturbances in their relationships, which serve as proximal precursors of depression. Depressive symptoms further undermine interpersonal functioning, leading to the perpetuation or exacerbation of depression and risk for recurrence. More specific models of risk explain the contribution of particular forms of adversity, such as maternal depression (e.g., Hammen, 2009b) and maltreatment (Alink, Cicchetti, Kim, & Rogosch, 2009), to youth depression.

In recent years, efforts to understand long-term risk have considered how early adversity interacts with recent stress to confer vulnerability to depression (similar to the interactive cumulative-effects model). According to a "stress amplification" model, childhood adversity amplifies depressive reactions to recent stress; that is, youth with a history of adversity are presumed to demonstrate higher levels of depression than those without a history of adversity when exposed to severe but not mild recent stress. According to a "stress sensitization" model, childhood adversity reduces an individual's threshold for depressive reactions to recent stress; that is, youth with a history of adversity are presumed to require only mild stress to trigger depression, whereas youth without a history of adversity require more severe stress to trigger depression. Mounting evidence supports stress sensitization models, indicating that youth exposed to early adversity (e.g., parental abuse/neglect, multiple forms of family disruption) are more likely than those with no history of adversity to become depressed following exposure to mild or moderate levels of stress (e.g., Harkness, Bruce, & Lumley, 2006). One interesting study revealed stress amplification effects in prepubertal girls, but stress sensitization effects in girls progressing through puberty (Rudolph & Flynn, 2007), suggesting changes in sensitization across the adolescent transition. Of note, the stress sensitization effect (at least when declines in the strength of association between life stress and the onset of depression across episodes are examined) appears to be most pronounced in those at low genetic risk for depression, perhaps because those with high genetic risk are already sensitized to an initial onset of depression even in the presence of low levels of life stress (Kendler, Thornton, & Gardner, 2001).

Pathways of Risk

Building on research documenting stress sensitization and stress amplification effects, contemporary efforts have explored specific pathways through which these processes unfold (for a review, see Goodman & Brand, 2009). One line of research focuses on the idea that a history of prolonged or severe adversity sensitizes developing brain systems so as to create heightened reactivity to stress later in life (for a review, see Gunnar & Loman, 2011). Another line of research suggests that early adversity induces risk through exposure to maladaptive parent socialization patterns and stressful interpersonal contexts that undermine the normative development of sense of self, coping skills, and interpersonal competencies, leaving youth vulnerable in the face of future stress or even causing them to generate stressful events and circumstances (for reviews, see Hammen, 2009b; Rudolph et al., 2008).

Supporting biological risk pathways, exposure to early adversity predicts future dysregulation of the HPA axis (e.g., Cicchetti & Rogosch, 2012; Rao, Hammen, Ortiz, Chen, & Poland, 2008), deviant neural processing of emotional stimuli (Cicchetti & Curtis, 2005; Parker, Nelson, & The Bucharest Early Intervention Core Group, 2005), atypical patterns of frontal lobe activity (Dawson et al., 2003), and compromised immune system functioning (Shirtcliff, Coe, & Pollak, 2009). In addition to these functional variations, recent research reveals that lifetime exposure to adversity predicts differences in brain structure, specifically smaller volumes in specific regions of the PFC; moreover, reduced PFC volumes mediate the link between lifetime adversity and poorer executive function (spatial working memory) in adolescents (Hanson et al., 2012). In turn, individual differences in brain structure and function and poorer executive function are linked to depression, thereby supporting the idea that disruption in the systems underlying emotion regulation, stress reactivity, and cognitive self-regulation can serve as one mechanism through which early adversity contributes to future affective risk (for a review, see Forbes & Dahl, 2005).

Supporting psychosocial risk pathways, early adversity (e.g., maternal depression, maltreatment insecure attachment) exposes youth to several forms of interpersonal disruption, such as maladaptive socialization of emotion, problematic parent–child relationships, and stressful contexts (for reviews, see Abaied & Rudolph, 2014; Hammen, 2009b; Rudolph et al., 2008). For example, depressed, maltreating, and insecurely attached parents show less adaptive responses to their children's stress and expression of emotion (e.g., Abaied & Rudolph, 2010a; Edwards, Shipman, & Brown, 2005; Shaw et al., 2006) and engage in more hostile and less positive parenting (for a review, see Abaied & Rudolph, 2014). It is not surprising, therefore, that these youth suffer from a spectrum of functional deficits linked to depression, such as ineffective regulation and expression of emotion, social-behavioral deficits (e.g., seeking of negative feedback, avoidant responses to stress), relationship disturbances (e.g., poor friendships, peer victimization), and a tendency to generate interpersonal stress (for reviews, see Abaied & Rudolph, 2014; Rudolph et al., 2008). Providing explicit support for psychosocial pathways, research supports models in which disrupted parent–child relationships, heightened stress exposure, and social competence deficits mediate the contribution of early adversity, such as maternal depression, to subsequent youth depression (Garber & Cole, 2010; Hammen, Shih, & Brennan, 2004). However, because these studies have not used genetically informed designs, it is difficult to tease apart the extent to which the transmission of risk is due to socialization versus shared genetic vulnerability.

Resilience in the Face of Risk

Exposure to adverse conditions early in life, including parental depression, clearly does not uniformly disrupt the successful outcomes or healthy development of all children. Although studies of risk and vulnerability factors and processes predominate in studies of depression and dysfunctional outcomes, some research has examined predictors of resilient outcomes (including absence of depressive and other disorders), as well as protective processes. The classic study by Masten, Best, and Garmezy (1990) reported a resilience profile not specific to depression outcomes that generally has been replicated in studies of children of depressed mothers: "[They have] a positive relationship with a competent adult, they are good learners and problem-solvers, they are engaging to other people, and they have areas of competence and perceived efficacy valued by self or society" (p. 425). Masten and colleagues (2004) also found that along with parenting quality, IQ and positive personal characteristics and coping styles were predictive of resilient outcomes in a longitudinal study of high-risk youth. In a sample of youth at risk for depression due to maternal depression, Brennan, LeBrocque, and Hammen (2003) found that positive quality of parenting was a significant predictor of resilient outcomes by age 15. Pargas, Brennan, Hammen, and LeBrocque (2010) also found that positive maternal parenting, higher IQ, and personal qualities of high self-esteem and social competence with peers were protective factors in youth resilience at age 20. In the same high-risk sample, Hammen and colleagues (2008) found that youth with early-onset depression who "desisted" from further depression during the follow-up of 5 years to age 20 had significantly more positive peer and family relationships and higher self-esteem at age 15 than youth who had early-onset depression and also went on to have a recurrent/chronic course to age 20. Southwick, Vythilingam, and Charney (2005) reviewed a variety of positive personal traits and attributes, as well as genetic, neurobiological, and neuroendocrine factors also likely to play a role in protection against depression in the face of stressful experiences.

Summary

Emerging theory and research implicate early adversity as a pervasive and potent contributor to depression, propelling youth along a risky pathway characterized by significant intrapersonal and interpersonal disturbances that both heighten sensitivity to and increase the likelihood of future stressful experiences, thereby promoting risk for depression. These psychological, biological, and interpersonal disruptions may help explain the intergenerational transmission of risk. As noted, however, early adversity and consequent risks could, in part, reflect a shared genetic liability that accounts for vulnerability to depression. Understanding the intersection between genetic and environmental risks associated with early adversity will be a key direction for future research. Moreover, it will be important to determine whether the negative consequences of early social adversity depend on the timing of exposure, or whether they emerge during particular developmental stages. Given research implicating the adolescent transition as a pivotal interpersonal context of risk for depression (Rudolph, 2009; Rudolph et al., 2008), the long-term legacy of early adversity may be intensified during this stage, perhaps crystallizing into more severe and/or persistent forms of depression. Further research should build on initial studies of resilience to study both resistance to depression and deflection of the course of depression to less severe trajectories.

AN INTEGRATIVE DEVELOPMENTAL MODEL OF YOUTH DEPRESSION, AND DIRECTIONS FOR FURTHER STUDY

This chapter acknowledges the significant expansion of empirical research, using improved and innovative methodologies, in child and adolescent depression. There has been an increasing focus on developmentally sensitive models, although significant questions remain about the applicability of adult approaches to diagnosis and conceptualization, how childhood- and adolescent-onset depressions may differ, and especially, how development and experiences alter the neural and neuroendocrine systems relevant to depression. Because adolescent-onset depression is the "prototype" of most adult depression that is studied and treated, further understanding of developmental considerations will be fundamental to understanding recurrent adult depression—in short, a reversal of the typical "downward extension" models of adult depression applied to children. Three key methodological goals are encouraged for future studies:

1. Greater refinements in definitional issues of "depression" that address the challenges raised by heterogeneity, comorbidity, and the arbitrary lines between clinical and nonclinical depression, including transdiagnostic and endophenotype strategies. Such strategies also will assist in addressing the important question of the specificity of depressive outcomes, and tell us what is unique to the understanding and prediction of depression.
2. A greater emphasis on empirical studies with longitudinal designs, which will more precisely illuminate changes in vulnerabilities and clarify their mechanisms.
3. Further integrative studies that include multiple domains of vulnerabilities, to address the complex, transactional associations among biological, emotional, cognitive, and interpersonal processes. Such models are not difficult to construct, but are very challenging to test and validate through empirical investigations.

Figure 5.1 depicts one multidimensional developmental model of depression. The model is intended to highlight the complex and reciprocal interplay among diverse etiological influences on depression. Drawing from our empirical review, we have articulated a version of a model designed to encourage future directions. Temporally, the model commences with the genetic and environmental vulnerabilities the child faces from birth (or from prenatal life). Early life adversities may include traumatic experiences and severe abuse, but often include the more common problems of family instability; exposure to parental mental disorders and dysfunctional behavioral patterns; economic and social disadvantage; and harsh, insensitive parenting. Such adversities often occur early in life, but tend to be fairly chronic. These adversities shape individual vulnerabilities in biological, emotional, cognitive, and interpersonal functioning. Future research should increasingly and more precisely characterize the ways in which adversities exert maladaptive effects—and, ideally, define how particular adverse conditions operate at particular developmental stages to promote depression specifically.

Genetic factors have excited considerable attention throughout many aspects of human health and behav-

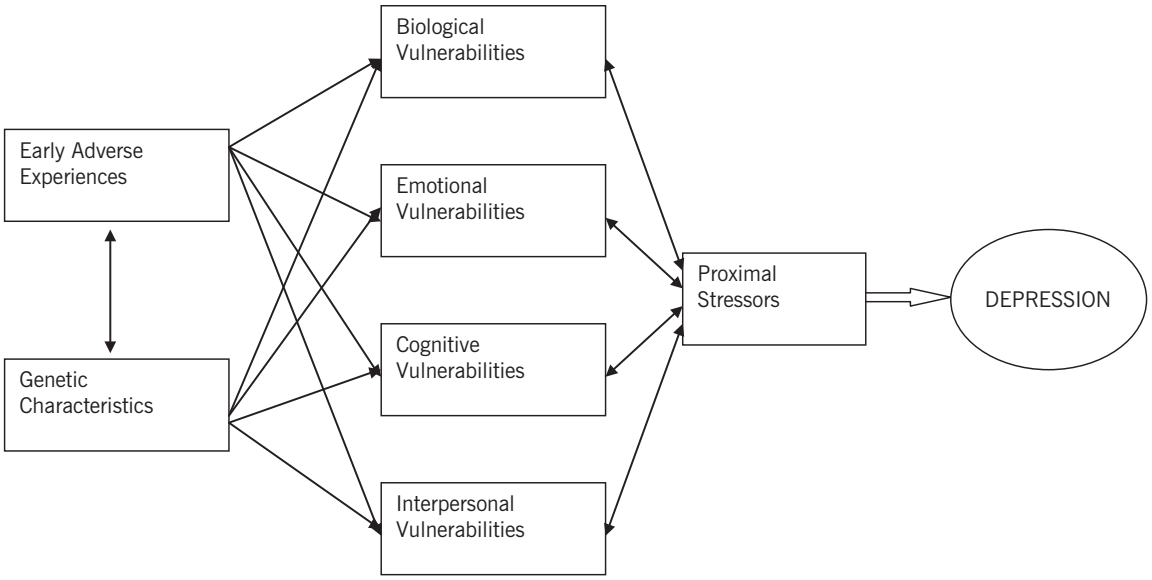

FIGURE 5.1. Multifactorial, transactional model of child and adolescent depression.

ior, and clearly represent a topic of obvious significance to our understanding of depression. There is substantial emerging evidence for heritable aspects of biological, emotional, cognitive, and interpersonal vulnerability. It is safe to predict that energetic efforts will be devoted to understanding the nature and mechanisms accounting for such genetic effects. In view of extensive evidence that the small effects of each of multiple genes are involved in human behavioral tendencies, the identification of candidate genes in youth depression along with the exploration of the various gene–environment interactions (and correlations) are likely to be of considerable interest to developmentally focused research.

The vulnerabilities depicted in Figure 5.1 are not meant to be exhaustive of possibilities for predicting risk for depression, but represent topics for which the literature so far has produced suggestive findings. Not shown in the figure because of their complexities are the multiple and bidirectional associations among the vulnerability factors themselves; nor is it easy to illustrate all the possible moderating and mediating pathways between the early adversity and genetic factors and the vulnerabilities to predict depression—although studies evaluating such complex pathways are clearly necessary.

In the model, the proximal predictor of depression consists of recent or ongoing stressful experiences, including both acute and chronic negative circumstances that typically trigger depression. Each of the vulnerability factors plays a role in how stress is construed or how it is processed at emotional and biological levels. Moreover, the vulnerability factors also play some role in the occurrence of stressors, not only in determining that an event is perceived as a stressor, but also in many cases contributing to maladaptive behaviors that cause stressors to occur. Also, individuals must deal with challenging circumstances but may lack the social, personal, biological, and cognitive resources needed to cope with or prevent stress effectively.

Depression is the outcome in the model, but it is also assumed that depression itself, as a commonly chronic or recurring condition, has deleterious effects on biological, emotional, cognitive, and interpersonal processes, thereby increasing or maintaining their likelihood for further negative impact on youth development. Imagine arrows issuing from depression back toward all the vulnerabilities, just as stress feeds both forward and backward. Indeed, a central question across levels of risk—including the biological substrate of depression—involves the effect of stress and prior

episodes of depression on the pathophysiology of depression. Depression is clearly a recurring problem for many sufferers, and perhaps depression experienced in adolescence represents a "degenerative" disorder that not only impedes normal developmental accomplishments but also heightens reactivity to future stressors.

The problem of depression in youth is a substantial one—not only because of its frequency and severity, but also because of the risk of a debilitating recurring disorder. Compounded with the impediments depression poses to achieving developmentally appropriate capabilities, depressed youth are likely to face their adulthood with impaired functioning in close relationships, parenting, and occupation, as well as emotional distress. We hope that further clarifications of etiological processes not only will serve the scientific goals of furthering the field's understanding of fundamental biological and psychosocial processes, but also will inform the interventions that are needed to interrupt the negative cycle.

CHAPTER 6

Pediatric Bipolar Disorder

ERIC A. YOUNGSTROM
GUILLERMO PEREZ ALGORTA

Our understanding of pediatric bipolar disorder has changed rapidly in the last two decades. A bipolar disorder over the course of a lifetime is uncommon but not rare, and serious but treatable. As we will see, the roots of bipolar disorder run through the perinatal period, and first episodes often occur in childhood and adolescence. These early stages of development hold the keys to prevention, early identification and intervention, and ultimately better outcomes for people affected by bipolar disorder and their families. Although most of this chapter's focus is on childhood and adolescence, the presentation is set in a larger context of lifespan development. "Bipolar disorder" here refers to the adult range, or what has been confirmed to be consistent across age ranges, whereas "pediatric bipolar disorder" (hereafter abbreviated as PBD) denotes findings based on child and adolescent data.

BRIEF HISTORICAL CONTEXT

The modern conceptualization of manic–depression, now called bipolar disorder, goes back more than a century. Even older historical references and descriptions of presentations exist, although the thinking about etiology was necessarily different. Aretaeus of Cappadocia (now Turkey) provided one of the earliest clinical descriptions around 150 A.D., and Hippocrates and Aristotle also wrote about what to modern eyes looks like mania (Angst & Marneros, 2001; Glovinsky, 2002). Cases of mania in children and adolescents have been recognized for as long as there has been a diagnosis of bipolar disorder (Anthony & Scott, 1960). Researchers have identified case notes from an asylum describing a manic episode in a young girl in 18th-century Liverpool (Findling, Kowatch, & Post, 2003). Kraepelin (1921) documented instances of childhood onset in his comprehensive tome, *Manic–Depressive Insanity and Paranoia*.

The boundaries of bipolar disorder have always been unclear. Kraepelin (1921) strove to distinguish manic–depression from dementia praecox, foreshadowing the continued debate about the boundaries among bipolar disorder, schizophrenia, and schizoaffective disorder (Craddock & Owen, 2010). The boundary between bipolar disorder and unipolar depression also has been ambiguous and contentious. More recently, there has been heated discussion about the relationship between bipolar disorder and borderline personality disorder (Paris, Gunderson, & Weinberg, 2007; Perugi et al., 2013). All of these disorders can involve profoundly disrupted mood, raising the question of what would be unique to bipolar disorder (MacKinnon & Pies, 2006).

A recent historical change is a substantial increase in the frequency with which bipolar disorder is diagnosed in youth. Prior to the 1990s, there was a smat-

tering of published case reports. The 1990s ushered in a combination of research and popularization that made the diagnosis much more salient. The result was a dramatic rise in the rate of clinical diagnoses of PBD. The number of office visits billed under a diagnosis of a bipolar disorder rose 40-fold in the span of two decades (Moreno et al., 2007), and data from the Centers for Disease Control and Prevention indicated that more than 50% of psychiatrically hospitalized children under the age of 12 carried clinical diagnoses of bipolar disorders by 2003 (Blader & Carlson, 2007). It is still hotly debated whether these increases reflect corrections for past underdiagnosis, mislabeling of different entities as PBD, or a faddish overuse of what should be a rare diagnosis. Critics have raised the concern that the popularity of the PBD diagnosis might be influenced by pharmaceutical marketing or other extrinsic interests (Healy, 2006; Youngstrom, Van Meter, & Algorta, 2010). The debate has continued through the revisions to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association (APA), with several position papers written to justify different approaches to the diagnosis in youth (Leibenluft, 2011; Youngstrom, 2009). DSM-5 (APA, 2013) advocates using a consistent set of criteria for children, adolescents, and adults, aligning with the recommendations of the International Society for Bipolar Disorders (Ghaemi et al., 2008; Youngstrom, Birmaher, & Findling, 2008). Although the idea of PBD is relatively new, the DSM definition has accrued considerable research investigating its validity; more than 9,000 peer-reviewed articles have been published at this writing, and more than 400 have been added to PubMed each year from 2008 onward. Some have also proposed creating a new diagnostic category for chronically irritable youth, in order to create a diagnostic alternative to expanding the concept of bipolar disorder (Leibenluft, 2011). DSM-5 has thus included a new diagnosis—disruptive mood dysregulation disorder (DMDD)—specifically to create an alternative to diagnosing PBD too often. Approaches to conceptualizing mood disturbance in youth are evolving rapidly.

DESCRIPTION OF THE DISORDER

Bipolar disorder is challenging to describe, due to its considerable heterogeneity. What does the clinical picture look like? Presentation runs the gamut from disinhibition and disorganization that are frankly psychotic, to periods of high energy associated with impetuousness but often large amounts of productivity, to episodes of severe and debilitating depression, as well as every permutation in between. Because of its episodic nature, it is also possible for a person to function within normal developmental limits during times of remission.

Definitional and Diagnostic Issues

The number of disorders DSM includes on the bipolar spectrum increased in DSM-III (APA, 1980), DSM-III-R (APA, 1987), and DSM-IV/DSM-IV-TR (APA, 2000), although DSM-5 (APA, 2013) stays with the same set of definitions as DSM-IV. The current nosology includes diagnoses of bipolar I, bipolar II, cyclothymic disorder, and other specified bipolar and related disorder (OS-BRD). The OS-BRD category subsumes the same prototypes that DSM-IV included under "bipolar disorder not otherwise specified" (BP-NOS), as well as adding a prototype of "short-duration cyclothymia." Both DSM-5 and DSM-IV also have designations for substance-induced manic symptoms and for manic symptoms due to another medical condition. However, unlike classification of most other disorders in DSM, correct classification of mood disorders (as we continue to call them, despite the fact that DSM-5 has dropped this category name) requires that the clinician first assess for the lifetime presence of mood episodes. Because mood disorders are episodic and often recurrent, the correct lifetime diagnosis may be tied to an index episode that occurred in the past. If a person seeks help for depression now, but had a manic episode years ago, then the depression is part of a bipolar illness, and the correct diagnosis would be "bipolar I, current episode depressed." Bipolar disorder is analogous to cancer, in that even when persons who are symptom-free are still labeled as having the disorder, albeit in remission. The nosology requires clinicians to evaluate lifetime history of depression, mania, hypomania, the potential for a mix of both poles of mood symptoms and periods of dysthymia in order to assemble the components for formal diagnosis of a mood disorder.

Bipolar disorder can lead to all possible mood states, whereas unipolar depression is distinguished by the absence of a lifetime history of hypomania or mania. Focusing solely on mania as the hallmark of bipolar disorder in general is problematic because (1) mania changes the lifetime diagnosis to bipolar I disorder, and thus, by definition, mania is not present in the other bipolar spectrum diagnoses; and (2) both youth and adults with

bipolar disorder tend to spend more time in depressed than in hypomanic or manic episodes (Axelson, Birmaher, Strober, et al., 2011; Judd et al., 2002). The burden of illness appears greater during the depressed phase in youth (Freeman et al., 2009) as well as adults (Judd et al., 2002), and people are more likely to seek help during periods of depression. Thus clinicians are more likely to see bipolar illness during states with pronounced depressive or mixed symptoms. Because this book has a separate chapter on depression (Hammen, Rudolph, & Abaied, Chapter 5, this volume), the diagnostic criteria for major depressive episode and dysthymia/persistent depressive disorder are not repeated here. It is crucial to remember that this organization of information does not reflect the clinical reality. Readers should approach Chapter 5 and the present chapter as a pair that need to be read together to have a comprehensive understanding of mood disorders—and depression and mania should not be compartmentalized in clinical practice or research. Similarly, it will also be valuable to consider persistent depressive disorder (APA, 2013), as dysthymic presentations often accompany depressive and bipolar disorders and are linked with substantial impairment.

Core Symptoms

The core symptoms of bipolar disorder involve dysregulation of mood and energy. Mood disturbance has been emphasized as a core feature of the illness, reflected in the "mood disorder" designation until DSM-5. However, the changes in energy and somatic aspects of the illness may be at least as important. Kraepelin (1921) described the disorder as influencing three major aspects of functioning, which he called "emotion" (now usually called "mood"), "intellect" (cognition), and "volition" (energy level). The DSM nosology has primarily focused on the affective component, with some acknowledgement of the cognitive and somatic symptoms. The DSM-5 revisions increase the emphasis on changes in energy, making them at least as salient as disturbance in mood. Energy changes are easier for individuals to observe in themselves, and are less prone to bias in retrospective recall (Angst et al., 2012). For these reasons, asking about changes in energy may be more sensitive to detecting hypomania than inquiries about mood. Increased focus on energy and activity also may reduce some aspects of cultural bias in assessment. Whereas framing in terms of "mood" is a very white, European, middle-class way of conceptualizing issues, other cultural groups often focus more on somatic elements of illness (Angst et al., 2010; Carpenter-Song, 2009).

Symptoms of Mania and Hypomania

The DSM-IV and DSM-5 criteria define a core set of diagnostic symptoms for mania and hypomania. Table 6.1 delineates the DSM-5 criteria for manic and hypomanic episodes. The distinction between hypomania and mania is primarily a matter of intensity, not quality. Hypomania is a clear change from a person's typical functioning, yet not so extreme as to cause marked impairment. If the behavior becomes severe enough to cause substantial problems, then it is considered mania instead of hypomania. Things are more ambiguous when mood is dysregulated but not causing impairment: If the person is able to function in school, and no one notices or is distressed by the intense emotional states, then it is less clear that it is pathological. A teen's raving to dance music for hours, or running alone pell-mell through the woods until exhausted, may not be evidence enough for hypomania or mania, despite its remarkable intensity in the moment.

A secondary distinction focuses on the duration of the mood state. The DSM-5 criteria specify that a manic episode is characterized by pronounced increase in energy and disturbance of mood much of the day, most days in a row, for at least a week. However, if the behavior is severe enough to warrant psychiatric hospitalization, then one need not have a week-long duration to establish the presence of a manic episode. Essentially, the minimum requirement is either a 1-week duration or hospitalization, whichever comes first. The criteria again become ambiguous in situations where hospitalization is not an option, due to factors such as the lack of access to a psychiatric facility. Then the behavior might be sufficiently disrupted to justify hospitalization, but results instead in arrest or no intervention at all.

For hypomania, the duration requirement is shorter, reflecting the general principle of hypomania being a diminution in degree of mania, rather than a qualitatively different state. The DSM-5 criteria have retained the durational threshold set at 4 days of clear change in mood or energy lasting much of the day, as previously operationalized in DSM-IV. Data from both clinical and epidemiological studies indicate that the modal episode length of hypomania is probably 2 days (Angst et al., 2011; Merikangas & Pato, 2009; Youngstrom, 2009). DSM-5 committees actively debated whether

TABLE 6.1. DSM-5 Diagnostic Criteria for Manic and Hypomanic Episodes

Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).

B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:

1. Inflated self-esteem or grandiosity.
2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
3. More talkative than usual or pressure to keep talking.
4. Flight of ideas or subjective experience that thoughts are racing.
5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
6. Increased in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal-directed activity).
7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).

C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

D. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or to another medical condition.

Note: A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a manic episode and, therefore, a bipolar I diagnosis.

Note: Criteria A–D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

Hypomanic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.

B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted, represent a noticeable change from usual behavior, and have been present to a significant degree:

1. Inflated self-esteem or grandiosity.
2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
3. More talkative than usual or pressure to keep talking.
4. Flight of ideas or subjective experience that thoughts are racing.
5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
6. Increased in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation.
7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).

C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.

D. The disturbance in mood and the change in functioning are observable by others.

E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.

F. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment).

(continued)

TABLE 6.1. *(continued)*

Note: A full hypomanic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a hypomanic episode diagnosis. However, caution is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for diagnosis of a hypomanic episode, nor necessarily indicative of a bipolar diathesis.

Note: Criteria A–F constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

DSM-5 has eliminated mixed episode as a distinct mood episode category. Instead, "with mixed features" is a specifier that can be used to modify any mood episode, including major depressive, manic, and hypomanic episodes. The mixed features specifier uses an algorithm that tries to focus on symptoms that are more specific to depressive or manic states, and exclude those that are potentially common to both mood polarities, when a clinician is determining whether the specifier should be used.

the duration should be shifted to 2 days instead of 4 days (cf. Towbin, Axelson, Leibenluft, & Birmaher, 2013). One point of view was that the 2-day duration risks inflating diagnostic rates of hypomania, and thus of some bipolar diagnoses. The contrasting position was that setting the threshold at 4 days reduces the sensitivity of the criteria, resulting in more false negatives that would be misclassified as having unipolar depression or some other condition. Duration criteria are directly relevant to issues of phenomenology in children and adolescents: One of the main reasons why many youth have been classified as having BP-NOS in several studies is the insufficient duration of the index mood episodes (Axelson et al., 2006; Findling et al., 2005; Youngstrom et al., 2008). Mood episodes in children sometimes are described as briefer than in adults, but the data indicate that adults frequently have 2-day episodes as well. The larger issue may be more that the 4-day or 7-day thresholds were not based on robust data (Dunner, Russek, Russek, & Fieve, 1982). Similarly, the scarcity of child psychiatric inpatient units means that severe behaviors often cannot lead to hospitalization, contributing both to misdiagnosis (Neighbors et al., 2007) and to the high rate of incarceration seen in adolescents with mood disorder (Pliszka, Sherman, Barrow, & Irick, 2000; Teplin, Abram, McClelland, Dulcan, & Mericle, 2002), particularly among ethnic minorities.

Symptoms of Depression and Dysthymia

Bipolar disorders usually involve periods of depressive symptoms—reaching the acuity of major depressive episodes in the case of bipolar I and bipolar II, or manifesting as "subthreshold" depression (due either to more mild or moderate severity, or to brevity of episode). Severe depressions lasting less than 2 weeks would fail to meet the durational criteria for a major depressive episode, for example. Again, we refer the reader to Chapter 5 of this volume to review the core symptoms and associated features of major depression, and to DSM-5 to review the criteria for persistent depressive disorder, as these symptoms also are central components of bipolar disorders. The DSM criteria for major depression and dysthymia (now called persistent depressive disorder in DSM-5) overlap, but are not identical. Hopelessness, for example, is considered a diagnostic symptom of dysthymia and not of major depression (APA, 2000, 2013). We suspect that this may have been an artifact of different measures being used in early studies, and that it then became reified in later definitions. The DSM bipolar definitions emphasize symptoms of depression (and do not specifically mention symptoms of dysthymia), but this also is probably an omission due to convention rather than driven by data. It is most likely to be problematic in the case of cyclothymic disorder, which in many respects is the bipolar analogue to dysthymic disorder (Van Meter, Youngstrom, & Findling, 2012).

The depressed phases of bipolar illnesses may show more "atypical" features (Goodwin & Jamison, 2007). Atypical depression is marked by hypersomnia instead of insomnia, increased appetite instead of decreased appetite, weight gain instead of loss, motor retardation or substantially decreased energy, and rejection sensitivity (APA, 2000, 2013). Rejection sensitivity may be a trait-like feature that is manifested regardless of current mood state (Davidson, 2007), whereas the other atypical features are limited to depressed states. At present,

no published data have specifically looked at whether atypical symptoms are more frequent in bipolar versus unipolar depression among youth with mood disorders. If this were the case, it would have considerable theoretical and clinical value. Conceptually, many of the atypical features cohere into a constellation of appetite, sleep, and energy-related symptoms that may indicate an "endophenotype," or an underlying set of features more closely tied to a biological process (Harvey, Mullin, & Hinshaw, 2006; Hasler, Drevets, Gould, Gottesman, & Manji, 2006). Clinically, atypical features might identify cases in which patients are seeking treatment for depression but are more likely to follow a bipolar course. Research addressing the atypical hypothesis would include (1) testing whether atypical symptoms are significantly more common among those with a history of hypomanic or manic episodes in addition to their depression; (2) testing whether atypical symptoms predict higher rates of "switching" to hypomania or mania in longitudinal studies or in acute treatment studies; and (3) examining whether atypical symptoms during depression correspond with contrasting disturbances during elevated mood states—such that increased appetite during depression corresponds with decreased appetite during mania, or depressive hypersomnia correlates with decreased need for sleep during mania. The first two research questions would have immediate ramifications for clinical assessment, whereas the third would help clarify mediational mechanisms by showing the extent to which atypical features are more linked to circadian sleep systems, appetite, or both.

Mixed Presentations

Mania and depression appear to be separate dimensions of mood functioning, not bipolar opposites along the same continuum. Mania is not "antidepression." Affective neuroscience indicates that positive affect and negative affect are virtually uncorrelated at the trait level, although the correlation may change at the state level (Carroll, Yik, Russell, & Barrett, 1999). It is possible for a person to experience high levels of positive affect, high levels of negative affect, elevations of neither ("euthymia," or functioning within normal limits), and high levels of both. Simultaneous elevation of positive and negative affect, or of manic and depressive symptoms, constitutes a "mixed state." It would be an oversimplification to reduce depression to high negative affect, or mania to elevated positive affect. Observers since Kraepelin have noted that mood disorders also involve changes in cognitive functioning, energy, and behavior, as well as mood. "Pure" depression would entail not just high negative affect, but also low positive affect, low energy, cognitive dulling and rumination, and low activity. Conversely, "pure" mania might involve high positive affect but low negative affect, high energy and activity, and the sense that cognition is accelerated. However, it is possible to have elevation or decrement on each component out of synchrony with the others, consistent with the moderate entrainment between cognitive, affective, and physiological systems (Izard, 1993). Kraepelin (1921) worked through the $2 \times 2 \times 2$ permutations implied by being clinically high or low on three facets; he thus described eight prototypical mood states, six of which would be mixed variants.

Clinical phenomenology confirms the prediction based on laboratory studies of affective systems: Blended states appear to be the rule, and pure presentations more of an exception (Van Meter et al., 2012). Many depressions involve high energy, often characterized as "agitated depression." Hypomania and mania often involve anger, frustration, or even rage—all negative in valence, although anger is an "approach"-oriented emotion in terms of cortical activity and behavioral correlates (Youngstrom, 2009).

There are two different temporal presentations that could produce mixed mood presentations. One involves the simultaneous occurrence of depressive and manic symptoms. This "dysphoric mania" often involves high energy coupled with negative valence. It is often volatile and can shift into other mood states quickly. Dysphoric mania is metaphorically like chocolate milk: The milk of mania and the chocolate of depression form a solution that is qualitatively different, and it is not clinically possible to separate components and say, "During this part of the day, John looked manic; and during this part of the evening, he looked depressed."

The alternate presentation is mood instability, oscillating between periods of relatively pure mania and depression. The metaphor in this instance would be fudge ripple ice cream, where the vanilla and fudge are co-mingled, but still distinct (Youngstrom et al., 2008). This conglomerate mood presentation often appears similar to the affective instability associated with borderline personality disorder, leading some to speculate that this personality disorder might be an extreme case on the bipolar spectrum with extremely brief mood episodes (MacKinnon & Pies, 2006).

Mixed presentations are clinically common in bipolar disorder generally, and may be even more frequent

in PBD (Algorta et al., 2011; Axelson et al., 2006; Duax, Youngstrom, Calabrese, & Findling, 2007; Kraepelin, 1921). They also are highly impairing, causing distress both to the affected persons and to the people around them. Mixed presentations carry great risk of suicide, as they pair the negativity and hopelessness of depression with the high energy and impulsivity that are more typical of mania (Algorta et al., 2011). Because they do not look like classic, "pure" depression or mania, they also are more difficult to recognize and diagnose correctly.

DSM-IV-TR criteria for a mixed episode (APA, 2000) required meeting full criteria for both mania and depression during the same episode (i.e., elated mood plus at least three B criteria, or irritable mood plus at least four B criteria for mania), along with at least five of nine depressive symptoms. The duration for a mixed episode followed the mania criteria: The episode needed to last 7 or more days, or to be severe enough to justify psychiatric hospitalization, rather than requiring 2 weeks for the depression. Concerns about the DSM criteria included that patients often showed mixed hypomanias, showing that the classification scheme was not exhaustive. In addition, DSM-IV(-TR) did little to describe mixed depressive presentations, and it also was vague about the number of hours in a day or the number of days in a week necessary to pass the threshold for diagnosing an episode.

DSM-5 has attempted to address these shortcomings by abolishing mixed episodes as a distinct episode type. Instead, "with mixed features" is a specifier that can be coded on top of a manic, hypomanic, depressed, or persistent depressive (previously "dysthymic") episode. If clinicians embrace the specifier, it could help to characterize mixed hypomanias more accurately, as well as to acknowledge the substantial portion of depression that involves mixed features. However, reviews of clinical diagnoses find that specifiers are rarely coded in practice (Garb, 1998). Thus the net result might be decreased clinical sensitivity to bipolar presentations. The DSM-5 algorithm for recognizing a mixed presentation tries to give more weight to symptoms specific to depression or mania. Irritable mood and poor concentration/distractibility do not count toward "with mixed features" in the DSM-5 framework (APA, 2013, pp. 149–150, 184–185) because they could appear in either pure depression or mania.

This approach faces several challenges: (1) It is more complex, making it less likely that clinicians will implement it consistently; (2) it was not tested against existing data to see whether the symptoms were in fact specific to one mood state; (3) nonspecific mood symptoms might actually be the most characteristic of mixed presentations; (4) the most impairing symptoms might be nonspecific (irritable mood is usually the top concern for parents and teachers initiating referrals); and (5) the algorithm ignores the possibility that a symptom might be qualitatively different during depression versus mania. Irritable mood or poor concentration could occur in both mania and depression, for example; but it is possible to distinguish manic from depressive presentations by the associated energy level and other contextual factors. Irritability during depression is a low-energy, grouchy, cranky presentation, possibly leading to lashing out if pushed; irritability during mania is high-energy and approach-oriented, and can lead to frustration when people set limits. Excluding irritability from consideration for "with mixed features" removes the potential to distinguish qualitatively different forms of irritability within each mood polarity. The complexity is made worse by having different criteria for the "with mixed features" specifier coded in the context of a manic or hypomanic episode (APA, 2013, pp. 149–150) versus a major depressive or persistent depressive episode (APA, 2013, pp. 184–185). The addition of a new "with anxious distress" specifier may further complicate the clinical description of mood presentations. Overall, empirical investigations of the new DSM-5 mixed features specifier (and other mood specifiers) will be crucial. Not only should this specifier's validity be examined, but how it is used in clinical practice should also be tracked.

Related Symptoms

A shortcoming of the DSM approach to diagnosis is that it privileges certain symptoms as part of the diagnostic criteria, and demotes the other symptoms or associated features. Bipolar disorders are associated with high levels of stress and anxiety (Wagner, 2006). The fact that many of these anxious symptoms are not included on the list of criteria for depression or mania draws an artificial division between them. When a substantial number of anxious symptoms are present, then the clinician needs to decide whether to diagnose a "comorbid" anxiety disorder, or whether to attribute the anxiety to the mood syndrome and perhaps code the "with anxious distress" specifier (APA, 2013, pp. 149, 184). The DSM criteria are hierarchical: A mood disorder takes precedence as the explanation for symptom

clusters unless the symptoms are clearly manifested outside the context of a mood episode as well. However, clinicians' implementation of this principle varies widely, resulting in significant differences in the rate of "comorbid" anxiety disorders labeled among cases with bipolar disorders across different research groups and clinics (Kowatch, Youngstrom, Danielyan, & Findling, 2005; Wagner, 2006). Similar problems arise with psychosis and the fuzzy lines among bipolar disorders, schizoaffective disorder, and schizophrenia (Barnett & Smoller, 2009), or between impulse-control disorders or antisocial behavior and mania (Bowring & Kovacs, 1992).

Types and Subtypes

DSM-5 retains the same broad set of bipolar disorders as in DSM-IV-TR, but with some modifications to criteria. We review those first, noting any modifications in DSM-5, and then briefly discuss alternate subtypes and nosologies. Because almost all published research reviewed here has used the DSM-IV criteria, they are presented as well. DSM-5 modifications currently have less of an evidence base than the DSM-IV definitions.

Bipolar I Disorder

DSM defines bipolar I disorder by the occurrence of at least one lifetime manic episode. Any and all of the other mood states described above are also possible in bipolar I, but the history of a manic episode defines the disorder as bipolar I. As noted earlier, if a person has had a previous manic episode but currently meets criteria for a pure major depressive episode, DSM would code this presentation as "bipolar I disorder, current episode depressed." This approach's strength is its recognition that the depression or other mood states may show a different response to treatment and follow a different course than would be expected if they did not occur in the context of a bipolar illness. An inherent challenge is that the definition subsumes tremendous heterogeneity. What does bipolar I look like? It may appear as florid mania, severe mixed mood, hypomania, depression, euthymia, or a blend of different aspects of each. The complexity increases when the element of time is added. Some people have long episodes, and some have frequent relapses; others have long periods of high functioning. Some may only experience a single manic episode in their lifetime; others have a predominance of depression; and some may have recurrent mania with no history of depression. At present, it is unclear whether these longitudinal courses reflect different subtypes of illness. It appears likely that they have different prognoses, but it is not well established that they show differential treatment response. The more distinct the mood episodes, and the better the functioning before or between episodes, the better the response may be to lithium (Alda, Grof, Rouleau, Turecki, & Young, 2005; Duffy et al., 2002).

DSM-IV also allowed bipolar I to be coded in the presence of a mixed episode. As discussed above, DSM-5 reclassifies such a mood episode as mania "with mixed features," while still assigning a lifetime diagnosis of bipolar I. The *International Classification of Diseases* (ICD) has required multiple episodes of mania to confirm a diagnosis of bipolar I. Faced with a single manic episode, ICD would indicate coding a "provisional" bipolar diagnosis (World Health Organization, 1992). This more conservative approach has probably contributed to lower rates of bipolar I disorder in studies using ICD instead of DSM criteria (Dubicka, Carlson, Vail, & Harrington, 2008).

Bipolar I is by far the most studied form of bipolar illness, and research on it comprises the bulk of the clinical trials addressing the bipolar spectrum. However, it only represents roughly a quarter of the cases meeting criteria for a bipolar disorder according to DSM criteria, and an even smaller portion if alternative criteria are used (Merikangas & Pato, 2009).

Bipolar II Disorder

From a clinical perspective, bipolar II disorder is best considered a form of depressive illness. To receive a bipolar II diagnosis, a person needs to have met full criteria for both a hypomanic episode and a major depressive episode. In DSM-5, either or both of the hypomanic and depressive episodes could also carry the "mixed specifier." The person is much more likely to seek treatment during the depressed phase of the illness, and the depression will generate much more impairment than the hypomania, by definition (Berk & Dodd, 2005). The person can also develop subthreshold mood problems, such as minor depression, brief hypomanias, or even persistent depressive dysthymia—corresponding to the "double depression" noted when dysthymia and major depression affect the same individual sequentially (Klein, Taylor, Harding, & Dickstein, 1988; Van Meter et al., 2012). The person cannot, however, display a full manic episode, or else the diagnosis must be changed to

bipolar I. Clinical observers note pronounced affective instability in many cases of bipolar II disorder (Berk & Dodd, 2005). The DSM-5 "with mixed features" specifier may help document this aspect of phenomenology.

Cyclothymic Disorder

DSM-5 retains the diagnosis of cyclothymic disorder from DSM-IV-TR. The definition specifies that the person shows pronounced hypomanic and depressive symptoms for an extended period of time—2 years or more in adults, and 1 year or more in youth, with the symptoms present more than half of the time and no more than 2 months symptom-free. DSM-5 has clarified that the hypomanic symptoms do not need to meet criteria for a hypomanic episode. The cyclothymic mood disturbance is associated with impairment. DSM is ambiguous about whether the mood presentation entails a distinct change from the person's typical functioning. There is conceptual debate about whether cyclothymia represents a distinct disorder, akin to dysthymic disorder, or would be better conceptualized as an affective temperament (Parker, McCraw, & Fletcher, 2012). The temperament model could suggest that cyclothymic traits constitute a diathesis for development of a full-blown mood disorder. Alternately, cyclothymia might represent a prodrome of bipolar illness.

Clinically, cyclothymic disorder is difficult to distinguish because by definition it excludes the most extreme and clear-cut presentations. The hypomanic symptoms cannot become too severe or pronounced, or else they form a manic episode (and the diagnosis must be changed to bipolar I). Similarly, the depressive symptoms cannot progress to a full-blown major depressive episode, or else the diagnosis must be changed to bipolar II or major depressive disorder with mixed features. The long duration of the index mood state also makes it difficult to discern from the person's typical functioning (Van Meter et al., 2012). Perhaps for these reasons, the diagnosis of cyclothymic disorder has rarely been used in youth (Youngstrom, Youngstrom, & Starr, 2005), although research studies suggest that it can be reliably identified and shows validity in terms of associated features, course, and family history (Van Meter, Youngstrom, Demeter, & Findling, 2013; Van Meter, Youngstrom, Youngstrom, Feeny, & Findling, 2011). Moreover, epidemiological studies suggest that it is prevalent and typically highly impairing (Merikangas et al., 2007, 2011; Van Meter, Moreira, & Youngstrom, 2011).

Other Specified Bipolar and Related Disorder or Bipolar Disorder Not Otherwise Specified

DSM-5 has renamed all of the DSM "not otherwise specified" (NOS) diagnoses as "other specified" (OS), even if none of the specific criteria were changed between DSM-IV and DSM-5. In the case of bipolar disorder, the definitions of OS-BRD and BP-NOS are similar, with the exceptions noted for the mood states (e.g., more emphasis on change in energy; making "with mixed features" a specifier instead of an episode definition) and clarifications about the number of hours required to meet the "much of the day" threshold. OS-BRD also adds major depressive episodes to the prototypes involving insufficient duration of hypomania or insufficient number of hypomanic symptoms. If interpreted as making major depression a required element, then the OS-BRD definition would focus on cases missing criteria for bipolar II disorder due to insufficient duration or symptom number. It would not include a large number of other cases that would meet other research or clinical definitions of BP-NOS used in DSM-IV (e.g., Axelson et al., 2006; Findling et al., 2005). OS-BRD also adds a new, fourth prototype of "short-duration cyclothymia" for presentations lasting less than 24 months in adults, and less than 12 months in youth.

In light of these shifts in criteria, which in some respects narrow and in other ways expand the scope of OS-BRD, we use "BP-NOS" when referring to research based on DSM-IV criteria—both to be consistent with the terminology used in the research base, and to help differentiate evidence from this research from evidence based on newer studies using the new DSM-5 criteria for OS-BRD. The APA intends OS-BRD (and previously intended BP-NOS) to be a diagnosis of last resort, employed only after a clinician has systematically considered the other bipolar disorders and has established that a case does not meet strict criteria for each of them. However, the opposite often occurs in practice, as both clinicians and researchers have been found to invoke a BP-NOS diagnosis without systematically checking whether criteria for another bipolar disorder would be met (Dubicka et al., 2008; Youngstrom, Youngstrom, & Starr, 2005). This is particularly common with cyclothymic disorder, which has been frequently lumped together with other NOS presentations and labeled as "mood disorder NOS," even in research studies. Many practicing clinicians have also used the NOS label when a young person might meet criteria for bipolar I

or bipolar II, believing that the NOS label might be less stigmatizing or more likely to be reevaluated when the youth is older.

DSM-5 has made two other noteworthy alterations to the "NOS" options from DSM-IV. One has been to eliminate "mood disorder NOS," which did not differentiate between bipolar and unipolar depressive spectrum illness. Practicing clinicians frequently used this as an even softer potential bipolar spectrum diagnosis (Youngstrom, Youngstrom, & Starr, 2005). The other has been to add "unspecified bipolar and related disorder" as a new residual option, for use when "the clinician chooses *not* to specify the reason that the criteria are not met for a specific bipolar and related disorder" (APA, 2013, p. 149; original emphasis). If practice and reimbursement trends stay similar over the next several years, the "unspecified bipolar and related disorder" diagnosis will probably become one of the most frequently used in practice.

BP-NOS and OS-BRD involve hypomanic and perhaps depressive symptoms. As with cyclothymic disorder, there can be no history of full-blown mania, or else the diagnosis must be changed to bipolar I; and no history of major depression, or else the diagnosis must become bipolar II (or perhaps major depression with mixed features in DSM-5). To qualify as a psychiatric disorder, the symptoms need to be associated with significant impairment in at least one setting.

DSM-IV-TR provided examples of prototypes for different BP-NOS presentations. These included recurrent hypomanic episodes without any lifetime history of mania or depression. DSM-5 allows coding the "with mixed features" specifier on the hypomania if clinically appropriate in bipolar II, but this specifier is not listed as an option for OS-BRD or unspecified bipolar and related disorder (APA, 2013, pp. 148–149). Nevertheless, people exhibiting this symptom course are present in epidemiological studies (Merikangas et al., 2012), family history studies (Hodgins, Faucher, Zarac, & Ellenbogen, 2002), and studies of subthreshold mood presentations (Kwapil et al., 2000). These people rarely seek clinical services because their functioning often is either normal or superior, and their fluctuations in mood and energy are not causing significant problems (Klein, Lewinsohn, & Seeley, 1996). Thus this variant of BP-NOS/OS-BRD is of more interest for research than clinical purposes, although it could be informative about factors related to resilience and good prognosis.

A second variant of BP-NOS/OS-BRD has an insufficient number of symptoms to meet full criteria for the index mood episode. The insufficient number of symptoms definition is most widely used in epidemiological studies, where it is straightforward to reanalyze data using alternative operational definitions, such as combining disturbance of mood with at least one other manic symptom, or examining liminal cases that fall one symptom short of the DSM threshold (Lewinsohn, Klein, & Seeley, 1995). These definitions automatically are more prevalent than definitions requiring a higher number of symptoms, but they still are associated with high degrees of impairment (Merikangas & Pato, 2009).

A third variant of BP-NOS/OS-BRD fails to satisfy the durational criteria for the index mood episode. The person might manifest all the symptoms of mania, but these do not last for a week or result in hospitalization. In like manner, the hypomania might not last 4 days, the depression might never have lasted 2 weeks or longer, or the cyclothymic/dysthymic period might only have lasted for less than a year. These subthreshold durations are not problematic if there has been a past episode that satisfied the full criteria; in that scenario, the current mood problems would be coded as "partial remission." However, if no past episode has met full criteria, and the current episode does not achieve the durational criteria, then the technically correct diagnosis would be OS-BRD in DSM-5 (and BP-NOS previously). The clinical and epidemiological data about the lengths of mood episodes are relevant to this scenario. Many youth with bipolar symptoms show a sufficient number of symptoms and considerable impairment, but the discrete mood episodes do not persist long enough to surpass the DSM duration thresholds (Youngstrom, 2009). Clinical data indicate that this is a frequent presentation among young people, and epidemiological and clinical data show that it is a common occurrence among adults as well (e.g., Judd & Akiskal, 2003). The DSM-5 stipulation that a hypomanic episode must last at least 4 days thus has the potential to shift many cases that would otherwise meet criteria for bipolar II into the OS-BRD category.

Substance-Induced Manic Symptoms

DSM-IV instructed that instances of manic symptoms coinciding with the use of street drugs or psychotropic medications should be classified as "substance-induced mood disorder with manic features," instead of being labeled as bipolar I or II. When a person develops mood and behavioral activation while taking a drug, it

is ambiguous whether the symptoms are features of the chemically induced "high," whether they are unintended side effects of the medication, or whether the medication is exposing a bipolar diathesis (Joseph, Youngstrom, & Soares, 2009). Many authorities suggest that behavioral activation while taking an antidepressant or stimulant might be a diagnostic indicator for a bipolar disorder (Akiskal et al., 2003; Ghaemi, Hsu, Soldani, & Goodwin, 2003). However, two reviews of the literature on antidepressant-induced "switching" into mania concluded that the evidence was most consistent with a "vigilance" hypothesis; that is, taking the medication was probably associated with better monitoring for potential hypomanic symptoms (Joseph et al., 2009; Licht, Gijsman, Nolen, & Angst, 2008). The appearance of high rates of treatment-emergent affective switching could be attributed to greater assessment sensitivity, as opposed to an underlying change in the rate of bipolarity. DSM-5 allows diagnosis of independent bipolar disorders in cases where the symptoms emerge during pharmacological treatment, particularly if mood symptoms precede the onset of substance/medication use, or if the symptoms persist for about a month after cessation of acute withdrawal or intoxication, or if there is other evidence consistent with an independent disorder (APA, 2013, p. 142). This would be consistent with a vigilance hypothesis, or with the idea that symptoms might be "breaking through" treatment. It also is consistent with the growing body of evidence that stimulants or antidepressants are not associated with higher rates of bipolar disorders or manic symptoms (Carlson, 2003; Pagano, Demeter, Faber, Calabrese, & Findling, 2008; Scheffer, Kowatch, Carmody, & Rush, 2005). However, the issue remains contentious (DelBello, Soutullo, et al., 2001), and it is possible that there may be a genetic predisposition associated with a subset of cases in which patients exhibit mood disinhibition when taking medication (Salvadore et al., 2010).

Narrow, Intermediate, and Broad Phenotypes of PBD

In response to the debate about the manifestations of bipolar disorder in children and adolescents, an influential paper delineated "narrow," "intermediate," and "broad" definitions of PBD (Leibenluft, Charney, Towbin, Bhangoo, & Pine, 2003). The DSM-IV criteria constituted the intermediate definition, and the narrow and broad definitions were departures from the DSM definitions. The narrow phenotype was largely based on the research operational definition used by Geller in her pioneering National Institutes of Health studies of PBD (Geller & Luby, 1997) at Washington University. The Washington University criteria required the presence of either elated mood or grandiosity in order to satisfy inclusion criteria for the bipolar group because irritable mood was nonspecific to PBD (Geller, Zimerman, Williams, DelBello, Bolhofner, et al., 2002). The Leibenluft and colleagues (2003) narrow criteria also adopted the focus on elated mood or grandiosity, along with requiring that the mood have clear episodic boundaries or fluctuations. Interestingly, the Washington University version of the Kiddie Schedule for Affective Disorders and Schizophrenia (WASH-U-KSADS; Geller et al., 2001) makes it difficult to track episodes because it focuses on the onset and offset of discrete symptoms rather than orienting inquiry around distinct episodes (Galanter & Leibenluft, 2008). There is debate about how many of the youth in Geller and colleagues' data would meet the episodicity requirement for the narrow phenotype.

The narrow phenotype was originally envisioned as a research definition, not something intended for clinical use. Subsequent studies have found that many adults with bipolar disorders present with primarily irritable, not elated, mood, suggesting that the narrow phenotype might exclude a substantial portion of adult bipolar cases (Judd et al., 2002). Conversely, pediatric studies find that elated mood and grandiosity are endorsed in the majority of cases meeting criteria for DSM-IV bipolar diagnoses if the symptoms are assessed systematically via semistructured interviews or rating scales (Kowatch et al., 2005). Elated mood and grandiosity are not the most impairing symptoms, and for that reason they are rarely seen as the main presenting problems (Freeman, Youngstrom, Freeman, Youngstrom, & Findling, 2011; Hawley & Weisz, 2003). Families tend not to focus on these symptoms in their spontaneous descriptions of their children's situations (Carpenter-Song, 2009). There are few differences between cases with and cases without elated mood in terms of severity, associated features, or other correlates when systematically assessed (Hunt et al., 2009). Requiring elated mood or grandiosity might not have huge effects on diagnostic rates or validity if done systematically; however, relying on unstructured interviews that concentrate on initial descriptions of the presenting problem is likely to mislabel a substantial portion of bipolar cases (Galanter & Patel, 2005; Jenkins, Youngstrom, Washburn, & Youngstrom, 2011). In the British National Institute for Health and Care Excellence Guidelines (*www.nice.org.uk/nicemedia/live/10990/30193/30193.pdf*), the narrow definition

of PBD has been adopted as the core definition, without specifying a corresponding systematic approach to assessment. This combination of factors has probably contributed to the low rate of clinical diagnosis of PBD in the United Kingdom (see Dubicka et al., 2008, for an example of differences in interpretation of clinical vignettes).

The broad phenotype of PBD initially described a presentation in which mood might be mostly irritable, without clear periods of elated mood or grandiosity (Nottelmann et al., 2001). The hallmark of the broad phenotype, though, was considered to be the lack of clear episodes (Leibenluft et al., 2003). The onset of illness might be gradual and insidious, or the mood dysregulation could be chronic to the point that a parent might report it was present "from birth" or even *in utero* (Papolos & Papolos, 2002; Wozniak et al., 1995). The lack of definite episodes set the presentation apart from the DSM-IV(-TR) definitions of bipolar I and II, which clearly required that the mania, hypomania, or depression be a change from the person's typical functioning that was readily observed by others (APA, 2000). The broad definition also was at odds with Kraepelin's (1921) conceptualization of mood disorder as episodic or cyclical, which he used to separate manic–depression from schizophrenia and other entities that followed a more progressive and unremitting course. Several research groups focused on irritable mood as a core feature of PBD and argued that nonepisodic presentations also were common on the bipolar spectrum (Mick, Spencer, Wozniak, & Biederman, 2005; Wozniak et al., 2005). There was suspicion that many cases clinically diagnosed with PBD also fell into the broad definition rather than the intermediate or narrow one, based on the fact that irritable mood and aggression were often the features driving referral and treatment (Blader & Carlson, 2007; Leibenluft, 2011). However, the service databases that showed increasing rates of clinical diagnoses of PBD did not distinguish among bipolar subtypes; nor did they track symptom-level details to isolate whether cases fit a narrow, intermediate, or broad phenotype.

Disruptive Mood Dysregulation Disorder

The broad phenotype started as a general characterization of PBD diagnoses that did not require elated mood, grandiosity, or episodicity. Leibenluft and colleagues (2003) offered a more precise operational definition of "severe mood dysregulation" (SMD) as a way of trying to increase the reliability of research diagnoses. SMD initially excluded cases with diagnoses of schizophrenia, pervasive developmental disorder, substance use disorder, or posttraumatic stress disorder (PTSD), as well as any cases with bipolar disorder or episodic symptoms of elated mood. A series of secondary analyses used somewhat different operational definitions, relying on combinations of items extracted from diagnostic interviews to characterize the irritable mood and aggression as being more chronic or episodic (Brotman et al., 2006; Leibenluft, Cohen, Gorrindo, Brook, & Pine, 2006; Stringaris, Cohen, Pine, & Leibenluft, 2009). In parallel, a new KSADS module established more precise interview stems and probes to follow the SMD definition, and this module identified a cohort of youth who participated in several National Institute of Mental Health (NIMH) neurocognitive and imaging studies (Rich et al., 2010, 2011), as well as a lithium trial (Dickstein et al., 2009). The more specific definition of SMD identified a group of patients who appeared distinct from youth with PBD in terms of affective response, functional imaging, and family history. The group with SMD also did not fare significantly better on lithium than on placebo in the one clinical trial. The secondary analyses of the longitudinal data sets using the chronic aggression definition found high rates of depression, but not elevated rates of bipolar disorder (although the sensitivity of these studies to hypomania and bipolar II may have been low; two studies were outliers in terms of bipolar disorder rates at baseline, and all relied only on self-report at the long-term follow-up, which is known to be less sensitive to hypomania; Youngstrom, Findling, et al., 2005).

DSM-5 has added the diagnosis of DMDD based on the available research with various operationalizations of SMD, combined with concerns about the high rate of clinical diagnosis and pharmacological treatment of PBD. The proposed definition of DMDD was changed several times through the DSM-5 development process, morphing from SMD to "temper dysregulation disorder" and then to DMDD; it was also moved from the disruptive behavior disorders group to the mood disorders group, where it ultimately was placed at the beginning of the depressive disorders section (i.e., not in the DSM-5 section on bipolar and related disorders). The DMDD definition in DSM-5 departs from the original formulations of SMD in several important respects, such as having fewer exclusionary criteria and fewer required symptoms. Many experts were concerned about including DMDD as a new diagnosis for clinical use, in the absence of any data about prevalence, longitudinal course, treatment response, or delinea-

tion from other disorders such as oppositional defiant disorder (ODD), based on the actual criteria recommended in DSM-5 (Axelson, Birmaher, Findling, et al., 2011). The field trial examining the reliability of the DSM-5 criteria in clinical practice found a kappa of .25 (ranging from .06 to .49 across three sites; Regier et al., 2013), indicating that it will be difficult to use the criteria to reliably distinguish DMDD from other mood and behavioral problems in clinical practice. For now, it is reasonable to infer that certain youths with severe irritability and mood dysregulation do not meet criteria for a bipolar spectrum disorder; however, more research is needed quickly to establish whether DMDD is distinct from other externalizing behavior problems, as well as to chart an appropriate course of treatment (Axelson, Birmaher, Findling, et al., 2011; Towbin et al., 2013). Clinicians working with DMDD should refer to this volume's chapter on conduct disorder (CD) and ODD (Kimonis, Frick, & McMahon, Chapter 3) to get a sense of the developmental factors likely to be at work.

Dimensional Models

The authors of DSM-5 originally intended to shift to more dimensional approaches for describing bipolar disorders and other forms of psychopathology (Kraemer, 2007). In the end, the DSM-5 criteria conserved the categorical definitions of bipolar disorders from DSM-IV, suggesting the addition of a severity scale to describe quantitative degrees of difference. The Research Domain Criteria (RDoC) initiative of the NIMH also emphasizes dimensional models (Insel et al., 2010). Behavior checklists, rating scales, and interviews evaluating the severity of mood presentations provide a natural way of quantifying the features of bipolar disorders. Taxometric analyses of both depressive and manic symptoms find strong support for a dimensional aspect of presentation, and latent class models tend to find graded classes of greater severity (Haslam, Holland, & Kuppens, 2012; Prisciandaro & Roberts, 2009, 2011; Tijssen et al., 2010).

Using dimensional measures avoids false dichotomies between major and minor depression versus other distress, or between manic and hypomanic presentations versus milder fluctuations in mood and energy. Dimensional and factor mixture approaches have major statistical advantages in terms of greater psychometric precision and improved statistical power, as well as the virtue of better approximating the structure of the underlying latent variables (Nylund, Asparouhov, & Muthén, 2007). However, dimensional models need to accommodate some complex aspects of mood disorders, including the possibility that past mood levels might moderate the treatment response or prognosis of present symptoms (Youngstrom, 2010). Dimensional models also need to be adjusted to reflect the issues of duration and recurrence (Klein, 2008); these are not especially well handled by categorical methods at present, either. The point is that simply measuring current mood symptoms will not be adequate for a complete understanding of bipolar disorders.

ASSOCIATED CHARACTERISTICS

Negative Affect

PBD has associated characteristics that are consistent with what would be expected from the literature for bipolar disorder in adults. PBD is linked with high levels of negative affect and high emotional reactivity (Walsh, Royal, Brown, Barrantes-Vidal, & Kwapil, 2012), consistent with the tripartite model of depression and anxiety (Joiner & Lonigan, 2000; Watson et al., 1995), as well as findings that bipolar disorder in adults correlates with higher trait emotional instability and neuroticism (Barnett et al., 2011). The high negative affect could be a mechanism for the elevated stress and anxious symptoms frequently observed in conjunction with bipolar disorder. The degree of state negative affect obviously varies with the phase of bipolar illness, being highest during depression and mixed states, average during euthymia, and lowest during euphoric hypomania or mania. The high trait levels, and the adult finding of high trait neuroticism even between episodes, indicate a propensity to experience negative affect that could contribute to the greater rates of mixed presentations and the preponderance of depressed moods over the long term for many cases. The levels of trait negative affect and neuroticism are also significantly higher in females after adolescence, reinforcing the propensity toward mixed and depressive presentations for them (Cyranowski, Frank, Young, & Shear, 2000; Duax et al., 2007).

Behavioral Activation and Inhibition

Gray (Gray & McNaughton, 1996) identified three different motivational systems that appear evident in mammals and have distinct neural circuitry: the behavioral activation system (BAS), the behavioral inhibition system (BIS), and the fight–flight system.

These systems overlap with other conceptualizations of motivational systems underlying mood disorders. For example, the BAS appears highly similar to Depue's behavioral facilitation system (Depue & Lenzenweger, 2006). These models have proven fairly robust, with measurement extending from self-report (Carver & White, 1994) through performance measures in humans and animals, down to metabolic correlates, distinct brain circuits, and potential genetic correlates (Sanislow et al., 2010). The BAS and BIS in particular have been examined in conjunction with multiple disorders, including attention-deficit/hyperactivity disorder (ADHD), ODD, CD, and anxiety disorders, as well as mood disorders in youth (Alloy et al., 2008; Fowles, 1994; Quay, 1993).

The BAS is loosely similar to a "gas pedal," providing drive towards cues of reward and impelling approach behaviors (including fun seeking, but also appetitive aggression). Mania and hypomania are correlated with high scores on measures of BAS, consistent with high levels of energy and goal-oriented behavior, as well as positive affect and also irritability and anger. Depression is associated with low BAS scores, aligning with predictions from the tripartite model of depression and anxiety. High self-reported BAS scores predict later emotional instability and progression to bipolar disorder (Alloy et al., 2012). One theoretical model of bipolar disorder is the "BAS dysregulation hypothesis," which posits that bipolar disorder involves a tendency toward extremely high or low levels of BAS activity (Alloy et al., 2008), perhaps resulting from greater sensitivity to cues of reward or loss (Urosevic et al., 2010). Sensitivity to cues of threat would implicate the BIS, and also would be consistent with high levels of anxious symptoms associated with bipolar disorder. These models have been most extensively researched in emerging adulthood and later, but recent supporting data extend into childhood and adolescence (Gruber et al., 2013).

Neurocognitive Performance

PBD is associated with multiple deficits in cognitive performance, including poorer processing speed, executive functioning, and working memory compared to those of healthy controls, along with more focal deficits in emotion processing (Joseph, Frazier, Youngstrom, & Soares, 2008; Walshaw, Alloy, & Sabb, 2010). Most of these deficits are intermediate in degree between those associated with schizophrenia and intact functioning in healthy controls (DelBello & Kowatch, 2003; Frazier et al., 2012); again, this is consistent with findings in the adult literature (Phillips & Vieta, 2007). Many of these cognitive dysfunctions are not specific to bipolar disorder. In addition to overlapping with the patterns of functioning in schizophrenia, there also is much similarity to the patterns observed with ADHD (Walshaw et al., 2010). However, studies large enough to compare subgroups with PBD + ADHD versus PBD alone or ADHD alone find that the comorbid group has the most severe deficits; this suggests that each disorder may be linked with additive, incremental impairment (Henin et al., 2007). One of the largest decrements in performance that may be relatively specific to PBD is decreased planning, measured by tasks such as the Tower of London (Walshaw et al., 2010). Overall cognitive ability tends to be in the normal range for youth with PBD, although the lower average levels of planning, set shifting, processing speed, and verbal working memory can contribute to academic difficulties. Unfortunately, the medications used to treat PBD also can affect cognitive performance, and medication status and diagnosis are often confounded in the extant studies, making it difficult to disentangle what may be state effects on test performance from trait markers of illness or collateral effects of medication (Henin et al., 2007; Joseph et al., 2008).

In regard to structural abnormalities, PBD has been associated with more white matter hyperintensities (Adler et al., 2006), disrupted circuitry in diffusion tensor imaging (Gonenc, Frazier, Crowley, & Moore, 2010), increased ventricular volume, reduced anterior cingulate volume (Singh et al., 2012), and decreases in amygdalar volume (Blumberg et al., 2005). The pattern of findings again is highly consistent with the literature on morphological changes in adult bipolar disorder, with the exception of amygdalar volume (Schneider, DelBello, McNamara, Strakowski, & Adler, 2012). Several studies find decreased amygdalar volumes in youth with PBD, whereas adult studies find increased volumes. Some speculate that the amygdalar findings may reflect effects of medication exposure (Chang et al., 2005), but this remains to be confirmed by prospective analyses (Pavuluri, West, Hill, Jindal, & Sweeney, 2009).

Multiple studies find that emotional processing is disrupted in PBD, as indicated by increased amygdalar activation in response to emotional stimuli, and also dysregulated activity in the dorsolateral prefrontal cortex and anterior cingulate—regions implicated in emotion regulation (Garrett et al., 2012; Pavuluri, Passarotti, Harral, & Sweeney, 2009). A few studies

have compared youth with PBD to youth with ADHD or other disorders in imaging studies, and have found some degree of specificity in patterns of activation (Lopez-Larson et al., 2009, 2010). Again, it is challenging to separate state and trait effects of bipolar disorder from comorbidity and from medication effects. However, the accumulated evidence offers strong support for the validity of research diagnoses of bipolar disorder as having measurable associations with neurocognitive performance, changes in brain functioning, and changes in neural circuits and morphology.

Sleep Disruption

Decreased need for sleep is a symptom of mania presenting in more than two-thirds of youth with PBD (Kowatch et al., 2005). People with bipolar disorder are more likely to show "evening" versus "early morning" diurnal activity patterns, and may be prone to circadian reversal, in which they stay up all night and sleep during the day (Hasler et al., 2006; Salvatore et al., 2008). Recent studies using parent checklists (Meyers & Youngstrom, 2008) and actimetry (Mullin, Harvey, & Hinshaw, 2011) find evidence of poor sleep quality and disrupted sleep architecture in youth with PBD, replicating and extending findings in the adult literature (Harvey, 2008; Talbot, Hairston, Eidelman, Gruber, & Harvey, 2009). Sleep disturbance also has been associated with ADHD and depression. What may distinguish PBD is the combination of having less sleep but maintaining a high energy level during periods of hypomania or mania (Geller et al., 1998; Luby, Tandon, & Nicol, 2007; Youngstrom et al., 2008).

Disrupted Relationships with Family and Peers

PBD is also associated with substantial disruption of interpersonal relationships, both with peers and within the family of origin. Mirroring the findings with bipolar disorder in adults, families and youth with PBD show high levels of expressed negative emotion, poor communication skills, and high levels of conflict (Algorta et al., 2011; Coville, Miklowitz, Taylor, & Low, 2008; Du Rocher Schudlich, Youngstrom, Calabrese, & Findling, 2008; Geller, Tillman, Craney, & Bolhofner, 2004). Recent studies with youth find substantial decreases in quality of life in terms of family and peer relationships (Freeman et al., 2009; Siegel, La Greca, Freeman, & Youngstrom, 2014). Interestingly, PBD appears to be associated with more performance deficits than knowledge deficits about social skills (T. R. Goldstein, Miklowitz, & Mullen, 2006). There are many plausible reasons why PBD would be linked with poor interpersonal relationships, several of which we discuss below in the section on developmental pathways.

Increased Risk-Taking Behavior

PBD is correlated with high impulsivity, particularly during periods of high energy. Hypomanic and manic symptoms are associated with increased risky sexual behavior, greater thrill seeking, and higher rates of alcohol and substance use in adolescents (Geller, 1999; Stewart et al., 2012). It is unclear whether the strong correlation between bipolar disorder and substance use is driven more by "self-medication" or by sensation seeking, but the association begins in adolescence and remains pernicious. The higher rates of substance misuse contribute to the rule-breaking behavior associated with hypomania and mania, in turn adding to the risk of arrest and incarceration (Pliszka et al., 2000).

COMMON COMORBIDITIES

Several different conditions consistently show high odds of comorbidity with PBD. Some of the common comorbidities probably expose methodological issues with current diagnostic practices, but others may provide a window into the underlying processes shared by what are putatively distinct conditions. Comorbidity can result from several different circumstances. One is coincidence: An individual could have the misfortune to experience two different illnesses at the same time, even though they are uncorrelated in the general population. However, if the two disorders show a statistically significant association with each other, there are still many other possibilities about the nature of the association.

Caron and Rutter (1991) delineated several different mechanisms for what they termed "artifactual" and "true" comorbidity, and others have generally retained and elaborated on these two categories (Angold, Costello, & Erkanli, 1999; Lilienfeld, Waldman, & Israel, 1994; Youngstrom, Arnold, & Frazier, 2010). Artifactual comorbidity can result from (1) referral biases, or changes in detection of conditions due to biases in surveillance and assessment; (2) categorizing dimensions, or creating artificial distinctions where there are not qualitative differences in nature; (3) overlapping

diagnostic criteria, in which the same symptom may count toward multiple different diagnoses; (4) artificially subtyping what actually may be a homogeneous entity, including instances where a developmental process shows heterotypic continuity; and (5) one apparent disorder's actually being a part of the other. Mechanisms for true comorbidity can include (1) shared risk factors; (2) comorbidity as distinguishing a subtype that shows different trajectories or treatment response; (3) one disorder's moderating the risk for the other; or (4) one disorder's being a developmental precursor or prodrome for the other. We depart from Caron and Rutter (1991) in treating the "early manifestation" model of comorbidity as a form of true instead of artifactual comorbidity, consistent with developmental approaches to psychopathology. The framework is a helpful way of organizing a large volume of information, and we use it as the scaffolding for reviewing the evidence about comorbidity between PBD and depression, psychosis, ADHD, disruptive behavior disorders (ODD and CD), anxiety, pervasive developmental disorders/autism spectrum disorder, and substance use. As the literature on comorbidity in PBD comes more into focus, it is evident that the patterns of comorbidity are congruent between PBD and adult bipolar disorder, once again reinforcing the validity of the pediatric construct (Robins & Guze, 1970).

Depression

It might seem strange to conceptualize depression as "comorbid" with bipolar disorder. However, hypomania and mania may have risk factors and etiological mechanisms that only partially overlap with those for depression (Johnson, 2005; McGuffin et al., 2003). Surveillance and referral biases complicate our understanding of the relationship between depression and hypomania or mania. In clinical settings where people self-refer for treatment, depression is more likely to motivate treatment seeking. For that reason, it often would be clinically more useful to consider hypomania or mania as a potential comorbidity for depression (consistent with the DSM-5 use of "with mixed features" as a specifier). Failure to assess systematically for a history of hypomania, combined with limitations of self-report as a source of information about hypomanic symptoms, may add to the difficulty in recognizing bipolar II and cyclothymic disorder. However, when referrals for youth are initiated by parents or teachers, they usually are focused on externalizing behavior problems or irritability in particular, and it could be clinically useful to remember that depression is often an associated feature worth assessing directly. There is heuristic value in studying depression and mania separately, and then examining potential interaction effects when they manifest sequentially or co-occur.

Of the different artifactual contributions to comorbidity, categorizing dimensions is clearly relevant, as is artificial subdivision. Taxometric investigations of the latent structure of both depression and mania find strong evidence of a major dimensional component to both, with more inconsistent evidence of categorical subtypes (Haslam et al., 2012; Prisciandaro & Roberts, 2011).

Of the true mechanisms for comorbidity, the mechanism of shared risk factors is relevant, given the substantial overlap in genetic, biological, and environmental and social risk factors for unipolar depression and bipolar disorder (Tsuchiya, Byrne, & Mortensen, 2003). Less is known about whether the risk factors for hypomania or mania might be distinct from depression, but if they are, then the mechanism of comorbidity as subtype gains credence. Bipolar II disorder is an example: The co-occurrence of hypomania differentiates a subtype of depression that might follow a different natural course and show a distinct pattern of treatment response (Berk & Dodd, 2005). The developmental sequencing model of comorbidity has some support, as depressive episodes often come to clinical attention prior to hypomania or mania, and some longitudinal data identify depression first (Duffy, Alda, Hajek, Sherry, & Grof, 2010; Reichart et al., 2004). However, low insight and poor sensitivity of many assessment methods to hypomania contribute to potential referral bias and surveillance issues. The idea that either hypomania/mania or depression may moderate the risk of the other mood polarity has been studied least to date. Earlier-onset depression may be associated with later development of bipolar disorder (Shankman et al., 2009), but the evidence that hypomania and mania may increase the risk of depression is generally somewhat stronger than vice versa (Youngstrom & Van Meter, in press).

Psychosis

Psychotic symptoms can occur during manic or depressive episodes. Due to the rarity of early-onset schizophrenia (see Kuniyoshi & McClellan, Chapter 12, this volume), mood disorders are actually the more common

causes of psychotic features in children and adolescents. Estimates of the rates of psychosis in PBD range from 0 to 88% (Kowatch et al., 2005). Two major factors influencing the rate are the definition of PBD used, and the definition of psychotic features. If a sample with PBD includes cases with cyclothymic disorder or bipolar II, then there should not be psychotic features, based on the definition of hypomania as excluding psychotic features (APA, 2013). Bipolar II disorder could have psychotic features during the depressed phase of illness, but psychosis during what would otherwise be a hypomanic episode would upgrade the severity to mania, and thus change the diagnosis to bipolar I disorder. Conversely, if the delusions and hallucinations persist outside the context of a mood episode, then the person might meet criteria for schizoaffective disorder, bipolar type. Schizoaffective disorder can be conceptualized as a comorbidity of schizophrenia and mood disorder, or as the most severe expression along a continuum of psychotic illness (Malhi, Green, Fagiolini, Peselow, & Kumari, 2008).

Even within bipolar I disorder, differences in definitions of psychosis have large effects on estimates. Whereas many operational definitions concentrate on hallucinations and delusions, Geller and colleagues also include severe episodes of grandiosity or elated mood, arguing that in extreme instances the severity of the symptom involves a loss of contact with reality (Geller, Zimerman, Williams, DelBello, Bolhofner et al., 2002). In an earlier study, this group also counted a symptom as present if either the parent *or* child endorsed it, applying a disjunctive algorithm without reinterviewing the dyad or filtering with clinical judgment (Tillman et al., 2008). Disjunctive approaches maximize assessment sensitivity and yield the highest rates of endorsement, but risk lowering assessment specificity compared to using conjunctive (e.g., requiring both parent and youth to report the symptom for it to be counted) or compensatory (e.g., using the average of the informants' perspectives) strategies (Youngstrom, Findling, & Calabrese, 2003). The combination of multiple alternative definitions of psychosis and a disjunctive strategy may help explain why the rate of psychosis reported by Geller's group (76% of cases with bipolar I; Tillman et al., 2008) is an outlier compared to rates found by the rest of the field, which are typically closer to 20–35% among cases with bipolar I (Kowatch et al., 2005). Other studies have used a definition focused on delusions or hallucinations, and have often used clinical judgment or compensatory methods rather than a disjunctive approach to reconciling differences in informant perspectives (Birmaher et al., 2006; Findling et al., 2001).

Assessing psychotic features may be even more challenging in youth than in adults because normally developing children may have unusual beliefs, magical thinking, and nonscientific explanations for events, due to their stage of cognitive development (Piaget, 1954). Similarly, adolescents often believe that they are exceptional and less vulnerable to mistakes, accidents, and illness, due to their developmentally normative sense of their "personal fable" (Alberts, Elkind, & Ginsberg, 2006). Ideally, any assessment findings suggestive of psychosis should be followed by evaluation by a clinician who has extensive experience with both normal development and current cultural references, as well as exposure to instances of frank psychosis (Arnold et al., 2004). Given the complexity of evaluating psychosis and the high rates of potentially false-positive findings, it would be prudent to treat apparent psychotic features as a "yellow flag" triggering further inquiry, rather than using them as sufficient evidence to change a diagnosis from hypomania (cyclothymic or bipolar II) to mania (bipolar I) (Youngstrom, Jenkins, Jensen-Doss, & Youngstrom, 2012).

Epidemiological data suggest that referral and surveillance biases may contribute to the apparent overlap between psychotic features and mood disorders, inasmuch as there appear to be people who experience hallucinations or delusional beliefs without co-occurring mood or cognitive impairment, and who do not seek treatment (Bentall, 2003). Overlapping diagnostic criteria and categorizing of dimensions are unlikely to add to the apparent comorbidity of mood disorders and psychosis. However, the subdivision artifact might be relevant in the case of schizoaffective disorder, which does not appear to have firm boundaries with either bipolar disorder or schizophrenia, challenging Kraepelin's distinction between the two (Craddock & Owen, 2010).

Attention-Deficit/Hyperactivity Disorder

ADHD is probably the most common comorbidity recognized among youth diagnosed with PBD. The rates vary markedly across samples, ranging from 15 to 98% among cases diagnosed with PBD (Kowatch et al., 2005). However, rates of PBD appear much lower in most samples ascertained for ADHD (Galanter et al., 2003; Galanter & Leibenluft, 2008; cf. Wozniak et al., 1995), and epidemiological and clinical epidemiologi-

cal samples tend to find modest associations between ADHD and PBD (e.g., Merikangas et al., 2012; cf. Arnold et al., 2012). Among adults, ADHD is proving to be a common comorbidity (Nierenberg et al., 2005; Wilens et al., 2003); again, however, the rate of co-occurrence appears most influenced by the base rate of each condition in the clinical setting, rather than reflecting strong shared etiology (Galanter & Leibenluft, 2008; Youngstrom, Arnold, & Frazier, 2010). Referral and surveillance issues are definitely distorting the degree of co-occurrence observed in samples with different ascertainment patterns.

There are several symptoms that could occur in either ADHD or mania, consistent with the artifactual mechanism of overlapping criteria (Klein, Pine, & Klein, 1998). In diagnostic parlance, these symptoms are nonspecific to either condition. High energy or activity level, poor concentration and high distractibility, and talkativeness or pressured speech all can be ambiguous, being commonplace in both ADHD and mania (Klein et al., 1998). Similarly, irritability is frequent among youth with ADHD, as well as being a diagnostic symptom of mania (Geller et al., 1998). However, the high rates of comorbidity persist even when researchers exclude these potentially "shared" symptoms, and comorbid cases show greater average impairment and other features consistent with having additive effects from multiple diagnoses (Biederman et al., 2013; Faraone, Biederman, Mennin, Wozniak, & Spencer, 1997). Geller and colleagues' (1998) emphasis on elated mood and grandiosity as cardinal features of pediatric mania was a method to try to improve the specificity of the PBD diagnosis. Elated mood that is clinically unusual in terms of frequency, intensity, or duration does appear to be highly specific to PBD across multiple samples and interviews (Freeman et al., 2011; Geller, Zimerman, Williams, DelBello, Frazier, et al., 2002). Grandiosity appears moderately specific, although it can seem similar to the narcissism and entitlement often shown by youth with CD or antisocial tendencies (Youngstrom et al., 2008). Hypersexuality is another symptom that is more specific to a smaller subset of diagnostic entities; it is most strongly associated with sexual abuse, mania, or exposure to sexually graphic material. All of the symptoms that appear more specific to mania tend to be ones that are less intrinsically impairing or immediately distressing to others (Freeman et al., 2011), with the result that they are often not prominent in descriptions of the presenting problem (cf. Yeh & Weisz, 2001).

A different (but potentially complementary) strategy from concentrating on diagnostically specific symptoms for differentiating between ADHD and manic symptoms would be to probe whether the symptoms have followed a more episodic course, displaying clear changes from typical functioning for the youth and coinciding with other notable shifts in energy and mood. The emphasis on episodicity helps distinguish mood disorders—characterized by changes in functioning—from other more chronic conditions. Otherwise nonspecific symptoms may offer more contrast when viewed through the lens of chronic versus episodic presentations. Difficulty concentrating, for example, is more suggestive of mania when it is not typical of the person, but is manifested at the same time as the person shows decreased need for sleep or episodic changes in mood or energy. More persistent impairment in concentration would be consistent with ADHD, or perhaps with some other chronic syndrome, such as an anxiety disorder (Youngstrom, Arnold, & Frazier, 2010).

Other potential artifactual explanations appear unlikely to explain much of the covariation between ADHD and PBD. The greater prevalence of ADHD (Merikangas et al., 2010) makes it impossible that it is a subtype of bipolar disorder, and there are enough instances of PBD without ADHD that PBD is certainly not an ADHD subtype. The two conditions are not simple gradations along the same continuum, either: Mania is qualitatively different from severe attention problems, involving other mood features not commonly implicated in ADHD (Youngstrom, Arnold, & Frazier, 2010).

When bipolar and ADHD criteria are both met in the same case, it is likely to reflect a true comorbidity—particularly when the diagnostician has been careful to establish that the hyperactivity, impulsivity, and inattention persist outside the context of the mood episodes, or that there is pronounced worsening during a mood episode. ADHD and PBD share many risk factors, including overlapping genetic risks (Asherson & Gurling, 2012; Faraone, Glatt, & Tsuang, 2003; Mick & Faraone, 2009), pre- and perinatal risks (Tsuchiya et al., 2003), and possibly disrupted neurocognitive systems. ADHD and PBD show similarities in neurocognitive impairments, such as those in executive function and working memory (Walshaw et al., 2010) and several similar brain regions are implicated in morphological and functional imaging studies. Given that both ADHD and bipolar disorder are polygenic conditions, and that the environmental risk factors for both are nonspecific

and often overlap, one model of comorbidity is that of shared "building blocks" or shared mechanisms. It also is possible that specific constellations of symptoms might implicate a single underlying mechanism, and that this fundamental process might be disrupted in multiple disorders. Sleep, appetite, and energy are connected aspects of a circadian process with integrated hormonal and neurological regulatory systems, and disruption of this sleep–wake process may contribute to a broad variety of disorders. The model of shared "building blocks" offers a deeper conceptual explanation for comorbidity (Youngstrom, Arnold, & Frazier, 2010). In the case of ADHD and PBD, comorbidity is likely to reflect shared foundational components, but also to be the product of superficial methodological issues. If the assessment process does not discern whether the symptoms are episodic, or whether they co-occur primarily in conjunction with other mood and energy symptoms, then the rate of comorbidity will be spuriously increased. Conversely, failure to apply the hierarchical exclusionary criteria that DSM recommends (in which comorbid disorders are not diagnosed if the symptoms only occur in the context of a mood episode) also would inflate the apparent rate of comorbidity with ADHD, as a function of the nonspecific symptoms' getting counted toward both diagnoses.

Some believe that comorbid ADHD and PBD represents a distinct subtype (Biederman et al., 2013; Faraone et al., 1997). Data are inconclusive as to whether the co-occurrence represents simple additive effects, or whether it has firm diagnostic boundaries or a distinct treatment response or developmental trajectory. Similarly, there are not yet enough data to establish with confidence whether ADHD and PBD each moderate the risk for development of the other. Some have speculated that ADHD might be a prodrome for bipolar disorder (Tillman & Geller, 2006), but most longitudinal follow-ups of large ADHD cohorts have found that the vast majority of cases do not meet criteria for mania at long-term follow-up (Galanter & Leibenluft, 2008; Klein et al., 2012). It is likely that the ADHD studies may have missed some of the bipolar spectrum cases due to issues of forgetting, lack of insight, exclusive reliance on self-report, and other factors that contribute to poor sensitivity to hypomania (Angst et al., 2010); however, the Tillman and colleagues (2008) sample also may have had challenges in differentiating episodic from chronic symptoms, due to the structure of the interview—which could have blurred the boundary between the conditions (Galanter, Hundt, Goyal, Le, & Fisher, 2012). Overall, the data are consistent with a model of shared "building blocks," in which some of the risk factors and systems are implicated for both conditions, but other features may be distinct (Youngstrom et al., 2010).

Disruptive Behavior Disorders

Other disorders frequently comorbid with PBD are what were called the disruptive behavior disorders until the publication of DSM-5. ODD and CD are the two disruptive behavior diagnoses that have accumulated the most research, although clinicians have frequently used disruptive behavior disorder NOS and adjustment disorder with disturbance of conduct as billing diagnoses as well (Youngstrom, Youngstrom, & Starr, 2005). Less work has been done on genetic, physiological, or neurocognitive correlates of disruptive behavior disorders (although there has been investigation into antisocial personality disorder and psychopathy in adults; Blair, 2006).

Referral and surveillance biases probably play a large role in the pattern of comorbidity between disruptive behavior and mood disorders. Because externalizing behaviors frequently top the list of concerns motivating caregivers to seek services for children or adolescents (Garland, Lewczyk-Boxmeyer, Gabayan, & Hawley, 2004; Yeh & Weisz, 2001), youth with mood plus disruptive behavior issues are more likely to come to clinical attention than youth without apparent externalizing comorbidity. Consistent with the referral bias hypothesis, there appear to be adolescents and adults with histories of recurrent hypomania or even mania who do not have comorbid disruptive behavior disorders, and who do not seek services and may function well (APA, 2000; Cicero, Epler, & Sher, 2009; Merikangas et al., 2012).

Imposing artificial categories on underlying dimensions contributes to artificial comorbidity here as well, as shown by the research into the "bipolar profile" and externalizing scores on the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001). On the CBCL, groups of youth with PBD tend to score significantly higher on the Aggressive Behavior, Delinquent/Rule Breaking, Attention Problems, and Depressed/Anxious scales, along with the Externalizing Problems broad band, than comparison groups of healthy controls, youth with ADHD, and other youth receiving outpatient services (Mick, Biederman, Pandina, & Faraone, 2003). However, youth meeting criteria for ADHD, or

for ODD, CD, and other disruptive behavior disorders, tend to show moderate or clinical elevations on the same scales, as do youth with depression and comorbid ADHD (Diler et al., 2009; Meyer et al., 2009; Youngstrom et al., 2004; Youngstrom, Meyers, et al., 2005). Although bipolar diagnoses are associated with statistically significantly higher averages, there is a great deal of overlap in the distributions. Some clinicians and researchers may be focusing on extreme elevations of externalizing behaviors in assigning a bipolar diagnosis. Most clinically referred youth with PBD will have high parent-reported levels of externalizing problems, resulting in high diagnostic sensitivity of these scales (Youngstrom, Meyers, Youngstrom, Calabrese, & Findling, 2006); however, externalizing problems are linked with a wide variety of other socioemotional problems as well, leading to the low diagnostic specificity. To put this another way, externalizing problems are a developmental psychopathology outcome that can result from myriad different processes. Externalizing is the paragon of "equifinality" in developmental psychopathology, in which multiple developmental paths lead to similar behavior.

The scales and symptoms that show greater diagnostic specificity for PBD, discriminating it from disruptive behavior disorders and ADHD, indicate that PBD is not reducible to extreme externalizing (Youngstrom et al., 2006). Similarly, the differences in specific symptoms—such as decreased need for sleep, elated mood, and racing thoughts—show that PBD is not a type or subtype of disruptive behavior disorder. PBD possesses distinct features and follows a different longitudinal trajectory from that of ODD (Burke, Loeber, & Birmaher, 2002) or CD/psychopathy (Lynam et al., 2009). On the other hand, the critique of an artificial subdivision may apply to the new diagnosis of DMDD: The symptoms of DMDD overlap completely with ODD, and the difference in presentation may largely be a matter of severity and not qualitative differences (Axelson et al., 2012; Axelson, Birmaher, Findling, et al., 2011; Copeland, Angold, Costello, & Egger, 2013).

Equifinality creates much potential for confusion when clinicians are trying to assess bipolar versus disruptive behavior disorders. Irritability and aggression can be the product of dysregulated mood or of coercive interpersonal processes. Grandiosity can be a symptom of mania (Kowatch et al., 2005) or a reflection of a sense of entitlement/narcissism that is common among those with antisocial tendencies (Frick, Cornell, Barry, Bodin, & Dane, 2003). Disentangling these trajectories requires precision and careful thought about the context of the behavior. These issues shape differences in wording of checklists (Youngstrom, Meyers, et al., 2005) and variations in clinical training (Dubicka et al., 2008; Mackin, Targum, Kalali, Rom, & Young, 2006) that alter endorsement rates, inflating differences in diagnostic opinion and comorbidity rates (Kowatch et al., 2005).

Bipolar and disruptive behavior disorders may involve some true comorbidity. The conditions certainly share risk factors: Families with bipolar proband youths show elevated rates of antisocial behavior (Rende et al., 2007; Wozniak et al., 2010), and offspring of parents with bipolar disorder show higher rates of externalizing disorders, albeit the risk of mood disorder tends to be even higher (Birmaher et al., 2009, 2010; Hodgins et al., 2002). Mood disorder is a risk factor for externalizing behavior, too. Irritability is a more common presentation of depression than sad mood in young males (Poznanski & Mokros, 1994), and mood dysregulation directly perturbs interpersonal relationships, leading to peer rejection and contributing to increased familial conflict (Algorta et al., 2011; Du Rocher Schudlich et al., 2008). All of these in turn contribute to increased risk of aggressive and antisocial behavior (Dishion & Patterson, 2006). Intriguingly, the path could run in the opposite direction as well: Youth with high levels of externalizing behavior show elevated risk of depression at long-term follow-up (Brotman et al., 2006; Shankman et al., 2009; Stringaris et al., 2009). Our hypothesis is that if comorbidity here reflects a subtype, it is primarily a subtype defined by interpersonal processes, and less of a genetic nature.

Anxiety and Related Disorders

Youth with PBD tend to show high rates of generalized anxiety disorder, social phobia, separation anxiety disorder, panic disorder, and PTSD (Birmaher et al., 2002; Wagner, 2006). These are broadly consistent with results from adult clinical (McIntyre et al., 2006) and epidemiological studies, which also find high comorbidity among bipolar disorders, generalized anxiety disorder, and panic disorder (Merikangas & Pato, 2009). Estimates of the rates of comorbid anxiety within samples with PBD show extreme variation (Kowatch et al., 2005), again suggesting that methodological issues are at least partially confounding the findings. DSM-5 indicates that persons with bipolar disorders may have considerable stress and anxiety during hypo-

manic, manic, or depressive episodes, as well as during persistent depressive (dysthymia) or cyclothymic disorders. DSM-5 also stipulates a hierarchical approach to diagnosis, whereby a comorbid anxiety disorder should only be assigned if the anxious symptoms clearly persist outside the context of the mood episode (APA, 2013). DSM-5 has added the "with anxious distress" specifier to the mood disorder sections to provide a mechanism for coding the anxious features without adding otherwise unnecessary comorbid diagnoses. Differences in the extent to which clinicians and researchers enforce this hierarchical exclusion will lead to large swings in the apparent rates of comorbidity.

Referral and surveillance biases are likely to play a large role yet again. If adolescents are referring themselves for treatment, they are more likely to seek services when depressed and anxious; and if clinicians focus first on the anxious symptoms, then they are likely to diagnose an anxiety disorder and then "call off the search" for other diagnoses (the so-called "search-satisficing" cognitive heuristic; Garb, 1998). High anxiety levels are also associated with greater impairment in youth with PBD (Harpold et al., 2005; Sala et al., 2010; Wozniak, Biederman, Monuteaux, Richards, & Faraone, 2002), and so the anxious youth may be more likely to seek services (as observed in adult samples; Hamalainen, Isometsa, Sihvo, Pirkola, & Kiviruusu, 2008; Jacobi et al., 2004) and thus to be overrepresented in clinical samples (Berkson, 1946).

The mechanisms of categorizing dimensions and artificial subdivisions are also likely to be at work here. The tripartite model of depression and anxiety describes how the comorbidity between anxiety and depression reflects patterns on three underlying dimensions: negative affect, positive affect, and physiological hyperarousal (Clark & Watson, 1991). The negative affect dimension is shared across depression and anxiety disorders, representing a nonspecific component (Blumberg & Izard, 1986). Negative affect also is implicated in the depressed and mixed presentations of bipolar illness (Youngstrom & Izard, 2008). In the tripartite model, the diagnostically specific feature of unipolar depression is a low level of positive affect, corresponding to anhedonia (Chorpita, 2002). Bipolar depression also would have low positive affect, but hypomania and mania would be associated with elevations of positive affect. According to the tripartite model, the diagnostically specific dimension for anxiety disorders would be physiological hyperarousal (Clark & Watson, 1991). Subsequent work has found that physiological hyperarousal shows the strongest association with panic, with some phobias and obsessive–compulsive disorder showing greater associations with disgust instead (Davey, Forster, & Mayhew, 1993). However, dysregulation of positive affect and negative affect are clearly involved in both unipolar depression and bipolar disorders, and categorization of dimensions could contribute to the appearance of comorbidity with anxiety disorders (also entailing high negative affect). The possibility that bipolar disorders constitute a subset of anxiety disorders (or vice versa) appears unlikely, though: Each set of disorders involves additional dimensions of symptoms that are not central to the other. Bipolar disorders do not include physiological hyperarousal, disgust, or fear as core parts of their clinical presentation, for example (Youngstrom & Izard, 2008); and anxiety disorders do not include increased energy, decreased need for sleep, elevated positive affect, hypersexuality, or grandiosity as core features.

A developmental sequencing model of anxiety and bipolar comorbidity aligns with various sources of data. Studies of offspring of parents with bipolar disorders find high rates of anxiety disorders in the younger offspring (Birmaher et al., 2009; Hodgins et al., 2002). Longitudinal studies frequently find that generalized anxiety disorder precedes later major depressive episodes (Mineka, Watson, & Clark, 1998); and retrospective studies of bipolar disorders in adults find that many report meeting criteria for anxiety disorders prior to the onset of a full-blown mood episode (Kessler, Berglund, Demler, Jin, & Walters, 2005; Perlis et al., 2004).

Anxiety and bipolar disorders definitely share risk factors. Family studies find elevated rates of anxiety disorders in relatives of probands with bipolar disorders. Elevated trait negative affect, or trait neuroticism or emotional instability in a personality framework, are associated with both anxiety and bipolar disorders. The overlapping risk factors also extend to a more granular level. For example, the short allele of the serotonin transporter gene has been identified as a diathesis for both anxiety and mood disorders (Caspi, Hariri, Holmes, Uher, & Moffitt, 2010). Some have suggested that high trait negative affect, neuroticism, and generalized anxiety disorder may be different labels for the same presentation, and that this trait is a moderator that increases risk for developing other disorders. It is well established that anxiety disorders increase the risk of depression, and also the depressed phase of bipolar illness (Sala et al., 2012). Whether anxiety increases risk of mania is much less clear. The possibility that

comorbid anxiety denotes a distinct subtype of bipolar disorder is intriguing and as yet untested in the pediatric literature. Indirect evidence suggesting that it is possible comes from the adult literature on affective subtypes. Anxious temperament may be distinct from a hyperthymic temperament, with the latter showing a propensity for hypomania or mania but lower rates of anxiety disorders (Karam et al., 2010).

Pervasive Developmental Disorders/Autism Spectrum Disorder

A small number of studies report moderately elevated rates of comorbidity between pervasive developmental disorders (now redefined in DSM-5 as autism spectrum disorder or ASD) and PBD (DeLong & Nohria, 1994; Wozniak et al., 1997). These co-occurrences are unlikely to result from categorizing dimensions, or from artificial subdivisions being imposed on these dimensions. PBD is not associated with the same pronounced deficits in cognitive functioning as many cases of ASD are, or with major developmental delays in most aspects of social and emotional functioning. There is no evidence of a shared developmental sequence, where pervasive developmental disorders/ASD might be prodromes for mood disorders or vice versa. The most likely mechanism for apparent comorbidity is that pervasive developmental disorders/ASD are frequently associated with poor frustration tolerance, deficits in emotion recognition, and poor emotion regulation, all of which increase the risk of irritability and aggressive behavior. If clinicians give great weight to irritable mood and agitation in assigning a diagnosis of "mania," and they do not systematically assess other criteria, then it is likely that the resulting diagnosis of "PBD" will be a phenocopy that has superficially similar symptoms that result from a different etiology (Youngstrom, Arnold, & Frazier, 2010). However, there is some evidence that a shared etiological pathway could contribute to episodic mood dysregulation and other mood symptoms, in combination with cognitive disability and other symptoms of pervasive developmental disorder/ASD. The genetic microdeletion creating velocardiofacial syndrome (VCFS) results in mood dysregulation as well as cardiac problems, facial dysmorphia and cleft palate, and poorer cognitive functioning, for example (Papolos & Papolos, 2002), along with high rates of schizophrenia, ADHD, and autism (Gothelf et al., 2004; Kates et al., 2007; Murphy, 2002). Although the base rate of VCFS makes it unlikely to directly explain more than 5% of cases of PBD, it provides a potential example of how genetic or neurocognitive processes might contribute to multiple disruptions that create apparent comorbidity in subsets of cases (Youngstrom, Arnold, & Frazier, 2010). The prenatal teratogens and perinatal environmental risk factors that affect cognitive development are also shared across both disorders (Hack et al., 2002).

Obesity and Metabolic Syndrome

Cross-sectional studies find significant comorbidity between overweight status or obesity and PBD (Merikangas, Mendola, Pastor, Reuben, & Cleary, 2012). The relationship is complicated by the fact that many of the medications used to treat PBD are linked with rapid and profound weight gain (Correll, 2008b). However, studies of youth find that overweight status often precedes mood instability. Both obesity and bipolar disorder are correlated with the inflammatory cytokine response (Correll, 2008a; Correll, Frederickson, Kane, & Manu, 2008; Goldstein, Kemp, Soczynska, & McIntyre, 2009; Goldstein, Liu, Schaffer, Sala, & Blanco, 2013). Evidence is growing for a potential direct causal association, where greater abdominal fat leads to chronic inflammatory response that irritates blood vessels in the brain as well as the heart.

Obesity may have indirect effects on risk for mood disorders as well. Obesity decreases the age of onset for puberty (Biro, Khoury, & Morrison, 2006), which is as low as 8 years old for girls in the United States (Lee, Guo, & Kulin, 2001). The secular trend for earlier puberty means that the hormone cascade associated with puberty is happening at a younger age, out of synchrony with brain development. For example, the myelination of the prefrontal cortical regions happens in the late teens and is completed by the early 20s for most people (Shaw et al., 2008)—coinciding with the onset of menarche in societies with a non-Western diet (Parent et al., 2003). The earlier onset of puberty also brings with it changes in peer interactions that now may occur before the familial and community supports are ready (Ge, Conger, & Elder, 1996). In addition, obesity itself creates psychosocial stress, increasing the chances of teasing, peer rejection, and low self-esteem (Vander Wal & Mitchell, 2011). Unfortunately, the relationship is likely to be bidirectional, as some youth use eating as a coping mechanism, and social isolation may be associated with decreased participation in sports and with lower physical activity in general (Vander Wal & Mitchell, 2011).

Substance Misuse

PBD is associated with an elevated risk of substance misuse (Goldstein et al., 2008; Goldstein & Bukstein, 2010; Wilens et al., 2004, 2009). The association is not due to many of the usual potential artifacts: The diagnostic criteria for bipolar and substance use disorders are clearly distinct (APA, 2013). Substance use is not reducible to a dimension of mood dysregulation, and it is unlikely that all substance use is a subtype of bipolar disorder. The fact that many youth meet criteria for PBD before having any exposure to alcohol or drugs belies the possibility that PBD is a subtype of substance use disorder (Birmaher et al., 2006; Geller & Luby, 1997). Behavioral genetic studies also find that addictions have a heritable component that is independent of most other major psychiatric illnesses (Kendler, Davis, & Kessler, 1997).

Some of the other artifactual mechanisms identified by Caron and Rutter (1991) may still apply, however. Referral and surveillance probably distort the rates of comorbidity observed in different settings. Substance misuse may either worsen or mask underlying mood problems, increasing the rate of treatment seeking in some and delaying it for others (Jane-Llopis & Matytsina, 2006). There is evidence of gender differences in both substance use and treatment seeking in adults with mood disorders: Women are more likely to seek help, and men are more likely to drink and use other drugs (Potts, Burnam, & Wells, 1991). This is likely to contribute to the sex difference in rates of bipolar II disorder identified at clinics, as there is no evidence of sex linkage for bipolar II at a genetic level, yet it is recognized more often among women in clinical samples (Berk & Dodd, 2005). Furthermore, those with substance use issues but no associated mood problems are unlikely to present to a mental health setting, often encountering the substance treatment or forensic system instead. The extent to which these mechanisms play out in childhood and adolescence remains an important area for study.

The possibility that co-occurring substance use denotes a bipolar disorder subtype is plausible, but as yet there is no evidence of a clear boundary delineating it from other bipolar disorders. It also is unclear whether comorbid substance use should change the prescription for treatment: No studies have systematically examined comorbid substance use disorder as a moderator of outcome in adult—let alone pediatric—bipolar studies yet (Singh & Zarate, 2006), and a Cochrane Collaborative Systematic Review recommends initiating treatment of mood disorders whether or not adjunct treatment for substance use issues is available (Cleary, Hunt, Matheson, Siegfried, & Walter, 2008).

The most likely pattern of association is that PBD involves high levels of impulsivity and emotion dysregulation, which in turn increase the risk of experimentation with substance use. Problems with peer relations also may increase the chances of association with deviant peers, further raising the risk of substance misuse. There is the possibility of third-variable confounders as well: The high rate of ADHD among youth with PBD might be sufficient to explain much of the correlation between PBD and substance misuse, for example (Wilens et al., 2011). Even so, the large literature on mood disorders and substance use in adults indicates that mood disturbance contributes incrementally to increased substance use. Although the degree to which substance use increases mood disorder risk is less well established, reciprocal effects are likely once substance use starts, with misuse and addiction contributing to subsequent mood dysregulation and relational conflict (Wray, Simons, Dvorak, & Gaher, 2012).

DEVELOPMENTAL COURSE AND PROGNOSIS

There have been substantial advances in our understanding of the developmental course of PBD. As Figure 6.1 shows, there have been nine major prospective longitudinal studies to date, which have followed cases for periods from 2 to 22 years. Because of bipolar disorder's episodic nature, it is intrinsically hard to show developmental continuity in it. Cases with symptoms of hypomania or mania at early assessments consistently show high rates of depression, hypomania, and mania at later follow-ups. Eight-year follow-up data from Geller, Tillman, Bolhofner, and Zimerman (2008) found that more than 40% of youth showed a new episode of mania within the first 2 years after turning 18—a high incidence of "adult" mania early in follow-up.

Few epidemiological studies include prospective follow-up of PBD. This is an important gap in the literature because clinical samples may be focusing on more severe cases, and thus potentially biasing our estimates of recurrence risk or comorbidity. A secondary analysis of two large epidemiological samples in adults found evidence suggesting a possible group of cases that had manic episodes at the initial evaluation and no later episodes of depression or mania (Cicero et al.,

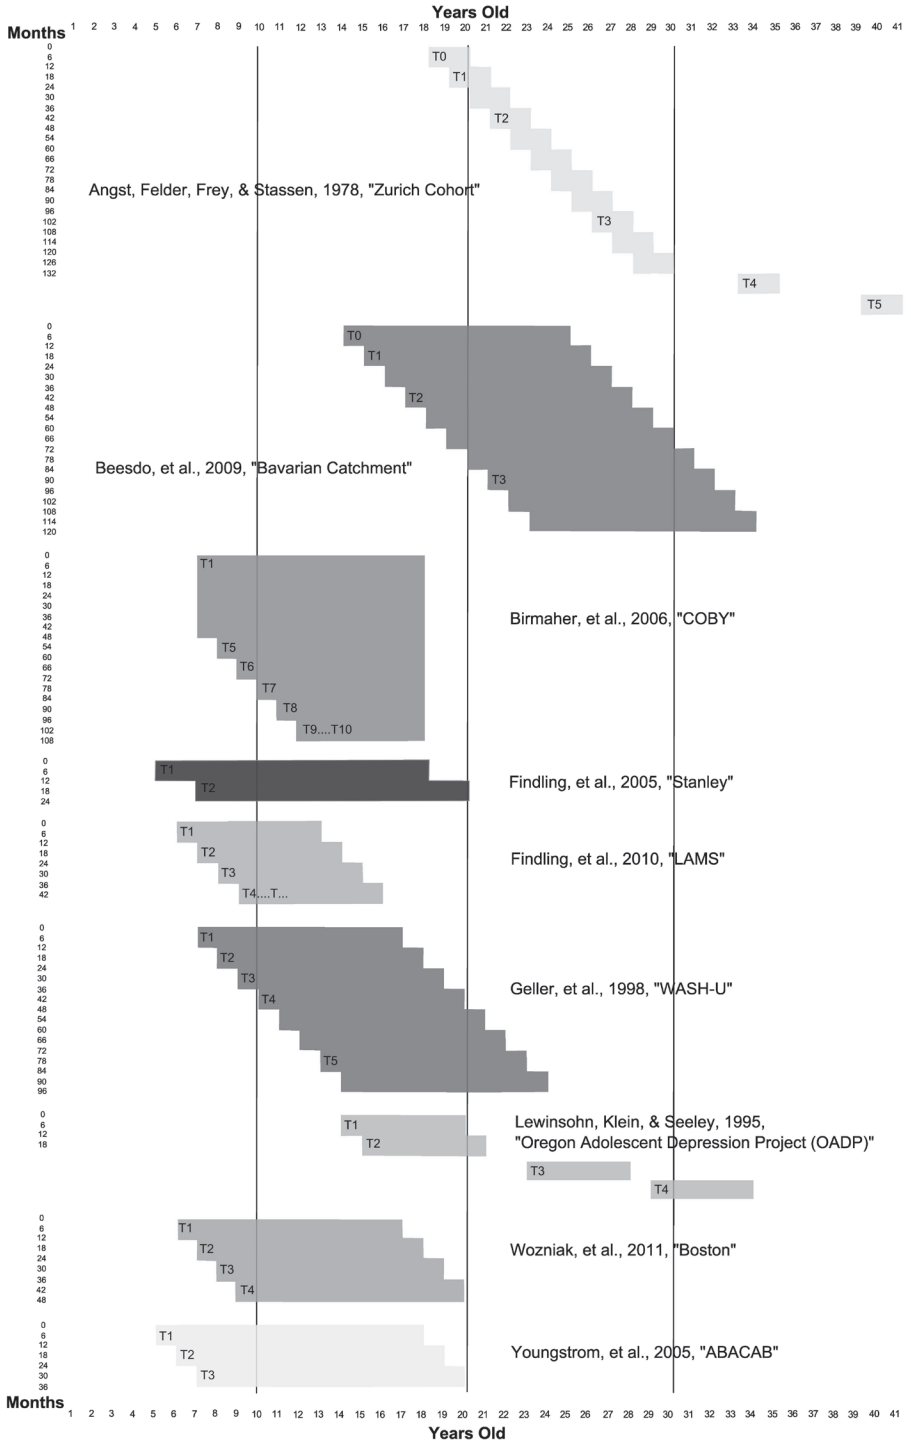

FIGURE 6.1. Prospective longitudinal studies of pediatric bipolar disorder.

2009). The pattern suggests the possibility of a "developmentally limited" form of bipolar disorder, in which affected persons might show mood lability or affective episodes as adolescents, and then grow out of the propensity to have severe mood issues as they develop better inhibitory mechanisms and emotion regulation (Cicero et al., 2009).

The "developmentally limited form" hypothesis inverts the traditional view that bipolar disorder is primarily an adult-onset illness. However, it is consistent with our growing understanding of neurocognitive development, including the tendency for affective regulation centers in the brain to myelinate fully in late adolescence and young adulthood (Gogtay et al., 2007; Shaw et al., 2008). The developmentally limited form hypothesis also is consistent with observations that hypomania and mania more commonly occur in younger age groups, whereas bipolar disorder in middle and later adulthood is primarily associated with depression, at least in clinical samples (Judd et al., 2002; Kraepelin, 1921). Epidemiological studies in adolescents identify some cases with histories of only mania or hypomania (Merikangas et al., 2012; Van Meter, Moreira, & Youngstrom, 2011). Prospective follow-up will be crucial to determine whether a significant portion of these cases show a benign prognosis. If so, then these developmentally limited cases often will not seek services, making them underrepresented in clinical samples. This in turn exaggerates our estimates of recurrence risk and poor prognosis, as we fail to gather data about those with a positive course and outcome. If there is a group that shows a good course, then this fundamentally alters our description of bipolar disorder from an incurable, recurrent, and potentially progressive illness to something in which we may be able to promote recovery by providing scaffolding to prevent severe problems until the emotion regulation systems reach full maturity. Strong analogies to other "developmental delay" models of pathology could offer innovative approaches to treatment.

Developmental Course in Clinical Samples

More data about developmental course are available from clinical samples (Axelson, Birmaher, Strober, et al., 2011; Geller et al., 2008). As noted above, naturalistic clinical samples may be biased toward exaggerating the risk of morbidity: Those who recover will not stay in treatment. This is an important caveat to consider when we review trajectories based on clinical samples. The child clinical data paint a picture similar to adult clinical data, suggesting high rates of relapse, continued service utilization, and possibly even a deteriorating course. It is unclear whether the recurrence and progression reflect changes in the environment, changes in the brain, or both. Neurological changes have gotten much attention in the form of "kindling" hypotheses, which posit that each mood episode changes synaptic connectivity in ways that increase susceptibility to future mood episodes, decrease the dependence on environmental triggers, and increase the resistance to treatment (Post & Leverich, 2006; Post & Weiss, 1997). An alternative hypothesis is that the neuropathy seen later in bipolar disorder may be the product of medication instead of the illness: It may be either the result of "self-medication" with street drugs and alcohol (which can induce cell death), or the effect of prescribed pharmacological agents on the developing nervous system (Schneider et al., 2012; cf. Hafeman, Chang, Garrett, Sanders, & Phillips, 2012). The pharmacotoxicity hypothesis argues that higher rates of substance use, including prescribed medications, may either trigger a bipolar diathesis or else cause neurological changes that create the potential for later mood dysregulation (Reichart & Nolen, 2004). Although some retrospective correlational data show an association between substance use (Post et al., 2010) or increased medication prescription (DelBello, Soutullo, et al., 2001) and earlier age of onset, other studies fail to find the same pattern (Pagano et al., 2008). There also are animal models demonstrating neuroprotective effects of lithium and other compounds (Manji, Moore, & Chen, 2000), leading some experts to argue for exploring prophylactic pharmacotherapy as a way of delaying or preventing the onset of full-blown mood episodes (Findling et al., 2007; Miklowitz & Chang, 2008). Prospective studies will be crucial to clarify the degree of evidence supporting each of these competing hypotheses, some of which are diametrically opposed, and all of which involve high stakes. More data about the risks and benefits of medication and other interventions will help people make better-informed choices about their treatment.

Age Differences in Phenomenology

There has been much discussion about whether bipolar disorder presents differently in children than it does in adults. Some have argued that earlier onset of illness is associated with increased mood lability, carbohydrate

craving, or oversensitivity to sensory input (e.g., Papolos & Papolos, 2002); other groups do not find significant associations between these variables and bipolar diagnoses. However, many of these speculative associations or differences have not had much investigation using semistructured diagnostic interviews to establish the criterion diagnoses.

More data are available testing the extent to which the DSM symptoms of mania are evident in youth meeting DSM criteria for a bipolar diagnosis. All of the DSM symptoms appear to manifest themselves in pediatric cases of hypomania and mania frequently (see Kowatch et al., 2005, for a meta-analysis), with relatively few symptoms appearing to show age-related effects in rate or association with the underlying mania factor. Manic symptoms appear to show a consistent factor structure, with a single major factor underlying symptoms in youth from age 5 through adolescence and adulthood (Frazier et al., 2007). In contrast, symptoms of depression appear to shift from a single global factor in children to a two-factor structure in adolescence (Frazier et al., 2007). Reliability for assessment of mood symptoms via semistructured interviews remained consistently high across the age segments studied.

In research testing for age cohort effects on the core depression and mania symptoms—as opposed to global severity scores—on several of the most widely used interviews, multiple symptoms showed significant effects of age even after investigators controlled for diagnosis and comorbid ADHD (Demeter et al., 2013). Age uniquely accounted for 2–4% of the variance in manic symptoms of motor activity, aggression, irritability, and bizarre thought content, and 8% of the variance in racing thoughts. The first three are likely to reflect normative developmental improvements in inhibitory control, and the other two reflect the higher rate of psychotic features in adolescent versus prepubertal samples. Age cohort uniquely explained variance in even more symptoms of depression, again reflecting a variety of developmental influences in addition to rates of depression and ADHD. Importantly, there were no significant age × diagnosis interactions for any of the 41 symptom ratings, indicating that the change in each symptom attributable to the presence or absence of mood disorder is stable across age ranges. Instead, the "background noise" contributing to elevations in symptoms for other reasons is what appears to change more with age.

Studies looking at parent reports on rating scales find that hypersexuality is more likely to be endorsed for adolescents than for younger children, and that problems with spending money impulsively are also more likely to be endorsed for older youth (Freeman et al., 2011). Both of these are highly face-valid observations. Item response theory analyses also indicate that irritable mood is one of the "easiest" items, requiring low levels of mania before parents are likely to endorse it, whereas psychotic symptoms require extremely high levels of mania (Freeman et al., 2011; Henry, Pavuluri, Youngstrom, & Birmaher, 2008). When adolescent and caregiver reports were compared, the underlying level of mania needed to be higher for the adolescents to endorse irritable mood in themselves, but teens were more likely to endorse hyperactivity or increased energy at lower levels of mania (Freeman et al., 2011).

Synthesizing all of the available information, we may conclude that younger clinical samples have higher overall levels of manic symptoms—partly due to higher rates of hypomania and mania, but also partly due to some symptoms' being inflated by other developmental factors (including, but not limited to, high rates of comorbid ADHD). Conversely, adolescent samples have higher rates of depressive symptoms—largely due to higher rates of depressive episodes, but also due to developmental changes' influencing the level of specific symptoms. However, the core symptoms associated with depression and mania appear consistent across age ranges, and they can be measured with good reliability via checklists and interviews. In the parlance of differential item functioning, mood symptoms do not show evidence of slope or factor loading bias due to age effects, but many mood symptoms do show modest age effects on averages after adjustment for mood diagnoses ("intercept bias"; Zumbo, 2007). The data indicate that there are not big developmental changes in the presentation of bipolar disorder within mood episodes, although some symptoms show age effects due to other factors. The biggest age effect on presentation of bipolar disorder is a shift in the propensity to experience episodes of mania versus depression.

EPIDEMIOLOGY

Prevalence/Incidence

Until recently, few epidemiological studies of children and adolescents systematically assessed symptoms of hypomania or mania. A meta-analysis found only 12 studies with usable data about rates of PBD, after re-

view of more than 1,500 titles and abstracts (Van Meter et al., 2011). However, more studies are adding mania modules to the diagnostic battery, and a consistent picture is emerging. The weighted average prevalence rate of bipolar spectrum disorder in youth averaged 1.8% across the 12 studies, which included 16,222 youth between the ages of 7 and 21 years ascertained during a period from 1985 to 2007. The rate of bipolar I disorder was 0.5%. The reporting of bipolar II, cyclothymic disorder, and BP-NOS was too patchy to allow estimation of separate rates. Intriguingly, the meta-analysis found no evidence of a secular trend for the rate of bipolar disorder to increase over the 22-year span covered by the included studies. The steady rate of bipolar spectrum illness in the community samples stands in sharp contrast to the marked rise in rates of clinical diagnoses over the same time period (Blader & Carlson, 2007; Moreno et al., 2007). Another unexpected finding was that the rates of bipolar spectrum disorder were equal in the United States versus the samples from other countries (Van Meter, Moreira, & Youngstrom, 2011). The data contradict the popular perception that PBD is isolated to the United States. Instead, the data fit the pattern of increased public awareness and clinical vigilance, consistent with what has been observed for ASD and other disorders (Joseph et al., 2009; Rutter, 2009). A more recent Canadian epidemiological sample corroborated the three major trends in the meta-analytic findings, with an overall rate of bipolar spectrum disorder of 2.1% among 15- to 18-year-olds (Kozloff et al., 2010).

It is difficult to disentangle meaningful signals about incidence versus prevalence in the current literature. Not all studies report incidence separately, and those that do use windows ranging from point prevalence to lifetime (Van Meter, Moreira, & Youngstrom, 2011). The heterogeneity in definitions of bipolar disorder and other design features swamp the differences attributable to shifts in index time period. However, across studies, several design features accounted for significant variance in the meta-analytic regressions: Studies including cyclothymic disorder or BP-NOS had significantly higher rates of bipolar spectrum disorder, and older participants had higher rates of bipolar disorder (Van Meter, Moreira, & Youngstrom, 2011). Rates of all bipolar spectrum disorders are higher in clinical settings than in the general community, and the rate of bipolar disorder tends to increase in more acute settings (see Figure 6.2).

Sex Differences

Studies in adults find no evidence of sex linkage for bipolar disorder, or evidence of differential prevalence rates, with the possible exception of bipolar II disorder's being more commonly diagnosed in women (Berk & Dodd, 2005). It is unclear whether the higher diagnosis rate among females is due to actual differences in incidence, or to patterns of treatment seeking or variations in diagnostic interviewing. Although there are plausible differences in psychosocial risk factors for depression, and possibly some hormonal mechanisms (Cyranowski et al., 2000), the poor sensitivity of unstructured clinical interviews to hypomania and the evidence that many people forget or discount past hypomania both contribute to misdiagnosis as unipolar depression.

Studies do find that men with bipolar disorder are more likely to experience mania, and that women are more likely to experience depressive and mixed episodes (Goodwin & Jamison, 2007). Pediatric data conform to this pattern, with younger males showing higher rates of mania, and adolescent females showing higher rates of depression; however, there are no overall significant sex differences in the rates of bipolar I disorder, cyclothymia, or BP-NOS (Axelson et al., 2006; Duax et al., 2007; Van Meter, Moreira, & Youngstrom, 2011). The cross-sectional data suggest a hypothesis that bipolar disorder may follow more of a recurrent depressive course in women, or that women show greater tendency toward an internalizing instead of an externalizing problem trajectory—but this remains to be confirmed with prospective data.

Socioeconomic Factors

Bipolar disorder shows a complicated relationship with socioeconomic status (SES). Older studies in adults originally found that bipolar disorder appeared more likely to occur among economically privileged groups, and schizophrenia more likely to occur among lower-SES groups (Goodwin & Jamison, 1990). More recent reviews conclude that much of this apparent association was due to diagnostic biases (Goodwin & Jamison, 2007), whereby ethnic minority and poorer individuals were more likely to be diagnosed with schizophrenia or antisocial behavior, and higher-SES individuals were more likely to be diagnosed with mood disorders (Strakowski et al., 1997). However, the data still do not find bipolar disorder overrepresented among the economi-

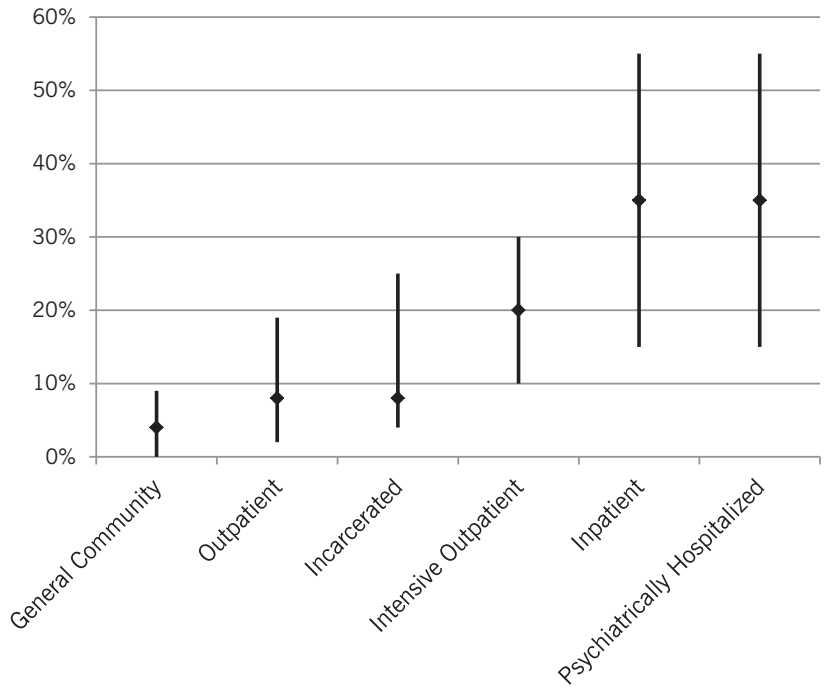

FIGURE 6.2. Median and range of prevalence rates for PBD in different clinical settings. Rates are based on prior reviews (Merikangas & Pato, 2009; Youngstrom, 2007; Youngstrom et al., 2009). Clinical settings are sorted into increasing intensity of services.

cally disadvantaged. It is possible that two opposing trends cancel each other out on average: Bipolar disorder appears linked to higher creativity and productivity, especially among family members of those affected (Johnson, Murray, et al., 2012). This would contribute to a positive association between bipolar disorder and SES. There is some evidence that professional or artistic success in a parent may be associated with mildly elevated risk of bipolar disorder in the offspring, consistent with this hypothesis (Tsuchiya, Agerbo, Byrne, & Mortensen, 2004). However, the devastating effects of the illness and the associated underemployment and unemployment often lead to poverty for the affected individual, and for families when a parent is affected (Lopez, Mathers, Ezzati, Jamison, & Murray, 2006).

The effects of SES are much more pronounced in clinical settings than in the epidemiological context. Consistent with findings in the adult literature, minority youth with bipolar disorder appear overrepresented in incarcerated samples when these are reassessed with semistructured interviews (Pliszka et al., 2000). African American and Hispanic youth with bipolar disorder are more likely to receive clinical diagnoses of CD or schizophrenia (DelBello, Lopez-Larson, Soutullo, & Strakowski, 2001). European American youth appear significantly more likely to receive medication than minority youths (dosReis et al., 2005), and more likely to receive prescriptions for mood stabilizers and atypical antipsychotics (Kowatch et al., 2013). These differences in diagnosis and service utilization may result from the interplay of cultural factors shaping beliefs about the causes of behavior and emotional problems, as well as differing views of what constitutes an "illness" for which medical treatment might be appropriate (Carpenter-Song, 2009; Yeh, Hough, McCabe, Lau, & Garland, 2004). Cultural differences in the description of the presenting problem may interact with a diagnostician's cognitive heuristics. When

an upper-SES family reports concerns about "mood swings," the initial clinical hypothesis may be a mood disorder. When a lower-SES family describes concerns about "behavior problems," then the starting hypothesis may be a conduct problem. Well-documented heuristics such as confirmation bias and search satisficing may then take over, generating the well-documented disparities in rates of clinical diagnoses (Garb, 1998; Jenkins, 2012).

Cultural Variations

Epidemiological studies in adults generally find similar rates of bipolar disorder across countries and within different racial and cultural groups within the United States. The Cross-National Collaborative Group study found lower rates of all psychiatric disorders in Asian countries, including lower rates of bipolar disorder (Merikangas, Jin, et al., 2011). This has been variously interpreted as being consistent with a greater focus on somatic aspects of illness than on emotional or cognitive components; as correlational evidence of the linkage between mood disorder and obesity or omega-3 fatty acids (in light of the substantially higher amount of seafood consumed in traditional Asian diets; Hibbeln, 1998); or as a consequence of heightened stigma towards mental illness (Hinshaw, 2006). Overall, the differences in rates are relatively modest.

Unipolar mania may be more common in some regions of the world, such as some Mediterranean regions (Yazici et al., 2002). There also are clear cultural differences in attitudes toward mental illness, treatment seeking, and specific behaviors. However, the few studies that have examined bias in specific measures or interviews, such as investigations of differential item functioning on measures of depression and mania, tend to find negligible evidence of bias. If people are left to seek services on their own, and then interviews concentrate on what people choose to volunteer and self-disclose, the effects of culture appear to be much larger than if people are systematically sampled and then complete a semistructured diagnostic interview or rating scale. When similar samples are asked the same questions, the differences in mood disorders appear much smaller than when culture guides the framing of the problems and the clinical encounters. Less is known about the extent to which these patterns prevail in child and adolescent age ranges, but the few investigations find consistent rates of bipolar disorder across African American, Hispanic, and European American youth when semistructured interviews are used in both epidemiological and clinical samples (Pendergast et al., 2014).

THEORETICAL FRAMEWORKS

Various theoretical frameworks have been proposed to explain bipolar disorder. Psychodynamic models posited mania as a defense mechanism against depression (Janowsky, Leff, & Epstein, 1970). Most researchers are not pursuing psychodynamic approaches actively at the moment, as biological models have become ascendant. Another notable omission is the lack of a behavioral/learning theory model of mania or bipolar disorder. Although behavioral interventions play a role in many psychotherapeutic packages, there has not been an overarching learning model or functional behavior analysis of mania. In general, bipolar treatment packages tend to comprise pragmatic assortments of techniques to reduce symptoms, and to improve coping and interpersonal functioning, rather than being organized around a major central theory.

At present, the majority of theoretical approaches toward bipolar disorder emphasize a strong biological component. Current theories avoid biological determinism, and articulate transactional models in which the biological and environmental factors interact and reciprocally influence each other to initiate and maintain dysregulated patterns of mood and energy; however, there is no model that fails to include some aspect of biology. Models emphasize different specific biological systems as core components of bipolar disorder. Some models emphasize the sleep system and circadian rhythm regulation (Harvey et al., 2006; Murray & Harvey, 2010). Others focus on basic motivational systems, such as Gray's BAS and BIS (Gray, 1986; Gray & McNaughton, 1996). Dysregulation of the BAS has been a particularly fruitful model, with accumulating evidence showing cross-sectional associations with mood symptoms in youth (Gruber et al., 2013), meaningful patterns of activation in imaging studies in adolescents and young adults (Nusslock et al., 2012; Urosevic et al., 2010), and longitudinal prediction of transition from at-risk to syndromal mood disorders (Alloy et al., 2008). Theoretical models also link BAS dysregulation with increased focus on cues of reward in bipolar disorder, and with increased emotional and behavioral activation following goal attainment, which may cascade into hypomanic or manic states (Johnson et al., 2000). Recent

work is also examining dysregulated positive affect as a core feature of bipolar disorder (Gruber, Eidelman, Johnson, Smith, & Harvey, 2011), as well as contributing to other mood and anxiety disorders (Carl, Soskin, Kerns, & Barlow, 2013).

Evolutionary psychology posits that depression may represent an adaptive mechanism to conserve resources and energy after an individual suffers a loss or rejection (Gilbert, Allan, & Trent, 1995). Emotion theorists have speculated that mania may represent a striving after goals that exploits initial opportunities or successes and attempts to amplify them, including greater interpersonal assertiveness and increased social dominance (Plutchik, 1980; Youngstrom & Izard, 2008). Depression may coincide with social rejection and loss of interpersonal influence (Gilbert & Allan, 1998). The emotional dimension of dominance may have a strong positive association with mood, with increased dominance coinciding with grandiosity and inflated self-esteem, as well as aggression toward challenges; in this view, decreases in dominance would coincide with depression (Demaree, Everhart, Youngstrom, & Harrison, 2005; Johnson, Leedom, & Muhtadie, 2012; Youngstrom & Izard, 2008). The emotion models extend prior work on the tripartite model of depression and anxiety (Clark & Watson, 1991), elaborating a greater role for positive affect in mania and mixed mood states. They also offer an organizational structure for integrating the RDoC with bipolar disorder, incorporating social dominance as well as the major domains of positive and negative affectivity (Sanislow et al., 2010). The BAS, sleep disruption (Mullin et al., 2011), and emotion models are each beginning to be investigated in PBD, with results that are so far consistent with expectations based on findings in the adult literature.

POSSIBLE DEVELOPMENTAL PATHWAYS

Bipolar disorder follows a developmental course. Even cases in which the first mood episode seems to appear from nowhere—an abrupt change from a previously high level of functioning—will have roots in biology and environmental factors that may be gleaned from family history or other sources. Cases with sharply defined episodes and good functioning between episodes also follow a developmental course. Mood episodes alter interpersonal relationships, often irreversibly; they may also lead to new biological set points and changes in neurocognitive functioning.

Our understanding of developmental pathways is similar to a partially completed jigsaw puzzle: There are several sets of variables that interlock, and we have assembled several groups of pieces, but we do not have the comprehensive picture solved. For example, neurological "kindling" has been advocated as a developmental model, in which each mood episode changes synaptic connectivity so that less environmental pressure is required to trigger subsequent episodes. The kindling model is consistent with evidence of progression, high rates of relapse in clinical samples, and decreased association between life events and triggering of subsequent episodes (Post, 2007). However, the kindling model does not yet integrate individual differences in temperament as risk or protective factors; nor does it comprehensively integrate models of normative psychosocial development or interpersonal interactions (Goodwin & Jamison, 2007).

Sleep dysregulation is another example of a cluster of related pieces. Only about 60% of youth meeting DSM criteria for any bipolar disorder show clear evidence of decreased need for sleep (Kowatch et al., 2005); for this subset, however, sleep disturbance is clearly linked with mood functioning. Genes related to circadian regulation are associated with bipolar disorder, and we also are learning about connections between sleep and metabolic functioning, which may exacerbate mood issues (Harvey, 2009). Sleep is linked to appetite regulation and weight gain, fitting cohesively with the patterns of symptoms seen in seasonal affective disorder and in atypical depression, which may be more common in bipolar depression in adults (Angst, Gamma, & Lewinsohn, 2002; Perugi, Fornaro, & Akiskal, 2011). Many of the brain regions implicated in sleep regulation also are regions of interest in bipolar disorder imaging studies (Harvey et al., 2006). Although many of the pieces are fitting together, we do not yet have a comprehensively elaborated model that connects the sleep system with other aspects of development.

A third cluster of pieces involves the relationship of psychosocial stressors, mood lability, stress generation, and substance use. Stress triggers mood, but mood lability and exaggerated emotional responses also tax interpersonal relationships and may lead to more rejection and stressful events (Rudolph et al., 2000). Mood and stress can thus create positive feedback loops. These loops appear to contribute to risk for substance misuse via multiple mechanisms. The "self-medication" hypothesis is a popular model clinically, suggesting that substance use may be a form of mood

regulation. Research support for this is moderate at present (Wray et al., 2012). A second developmental pathway for substance use would be via peer rejection's leading to association with more socially marginal or delinquent peers, who may provide increased opportunity for experimentation with substances. As reviewed in the section on comorbidity, shared third variables, such as impulsivity and poor executive function, add to the apparent correlation between mood and substance use.

A fourth cluster of pieces is accreting around motivation and interpersonal functioning. The BAS hypothesis (Alloy et al., 2008) and the social dominance model (Johnson, Leedom, & Muhtadie, 2012) both focus on how individuals prone to bipolar disorder may focus on cues of reward, or try to exert themselves socially, with successes feeding into a hypomanic spiral, and rejections or failures leading to intense emotional reactions and depression. The sensitivity to cues of rejection has also been noted in the context of atypical depression (APA, 2000).

As Table 6.2 shows, when we superimpose research on bipolar disorder with the epochs of typical development, we find that risk factors and correlates are present from conception through pregnancy and early infancy into adolescence and young adulthood, and that they continue to have reciprocal influences into late life. Juxtaposing the research with a developmental timeline reveals that bipolar disorder is not limited to a particular age range, defying the conventional separation of mental health research and services into "pediatric" and "adult" tracks. The table shows how the roots of what was previously been considered an "adult" illness stretch back before birth and into the prenatal environment. Comprehensive integration of a developmental psychopathology model will generate new and productive lines of inquiry with regard to bipolar disorder. Some possibilities include investigating the temperamental antecedents and moderators of risk for developing mood disorder in early childhood, or examining the role of androgens during the transition to adolescence and young adulthood. There are correlational data linking testosterone to social dominance (Bernhardt, 1997; Rowe, Maughan, Worthman, Costello, & Angold, 2004) and to mania (Ozcan & Banoglu, 2003; Pope, Kouri, & Hudson, 2000), raising the question of how much the higher androgen levels contribute to the greater rate of manic episodes in young males than in females. More work on the extent to which mania contributes to risk-taking behavior in adolescence, and triggers developmental "snares" such as pregnancy, traffic accidents, or other accidental injury, also looks promising (Stewart et al., 2012). Serious application of a developmental psychopathology framework will yield rapid progress filling in the gaps left by modern psychiatry's historic emphasis on biological models, adult manifestations, and tertiary intervention with acute illness.

RISK AND PROTECTIVE FACTORS

There are numerous nonspecific risk factors that produce small to moderate increases in the risk of developing bipolar disorder. These factors include genes of risk (which also are genes of interest for other disorders), poor maternal health during pregnancy, poor nutrition or substance use during pregnancy, stressful early environment, exposure to traumatic events, parental mood disorder, obesity, early onset of puberty, and early-onset depression (particularly with acute onset or psychotic features, disrupted sleep patterns, and adolescent substance use) (Goodwin & Jamison, 2007). There are correlations with peer rejection (Freeman et al., 2009; Siegel et al., 2014) and academic failure (Henin et al., 2007), which could represent risk factors, sequelae, or both. There are significant but weak associations with season of birth, leading to speculation about viral exposure or other mechanisms (Torrey & Miller, 2001). Low fish consumption is another factor that has prompted much interest. Omega-3 fatty acids are important in neural development, and higher rates of fish consumption during pregnancy are associated with lower rates of toddler and childhood aggression (Hibbeln et al., 2007). Later fish consumption correlates with lower rates of mood disorder and suicide at a global epidemiological level (Hibbeln, Ferguson, & Blasbalg, 2006). Effects appear modest at the level of current clinical trials, but the literature is changing rapidly (Freeman et al., 2006).

Family history of bipolar disorder appears to be the main exception to the general trend of nonspecific factors that contribute small to medium increases in risk (Tsuchiya et al., 2003). It is a robust predictor of pathology in general, but also shows further increases in the risk of developing bipolarity in particular. Reviews and meta-analyses conclude that there is at least a fivefold increase in risk of bipolar disorder when a first-degree

relative has bipolar disorder (Hodgins et al., 2002). These may be underestimates, as they are based on studies of offspring of parents with bipolar disorder, and the offspring had not been followed through the peak age of risk for onset of bipolar disorder. Conversely, the denominator of these risk estimates is derived from the rate of bipolar disorder in the general community; as epidemiological estimates rise, the size of the denominator increases, and the risk ratio or change in odds should decrease. One of the few studies looking at pedigrees with multiple family members affected found much larger estimates of risk (Gottesman, Laursen, Bertelsen, & Mortensen, 2010). The study was based on a Danish registry and hospitalization records. Thus the definition of bipolar disorder focused on severe cases and a relatively conservative definition, both of which may increase the strength of the signal.

Less is known about protective factors. Again, those that appear promising tend to be nonspecific. Greater cognitive ability in a youth or parent appears to be protective, possibly through compensation for difficulties and also through better navigation of health care systems (Gottfredson, 1997). Warmth and consistency in parenting, and better family communications, are likely to be protective, based on circumstantial evidence from longitudinal studies (Geller et al., 2008) and treatment studies where these are targets of intervention (Fristad, Verducci, Walters, & Young, 2009; Miklowitz, 2004). Healthy diet and regular exercise are also likely to be protective, based on the emerging evidence supporting the role of metabolic and inflammatory dysregulation in mood disorder. The "orchid" hypothesis is an interesting possibility, too: According to this model, the diathesis for mood sensitivity, coupled with a supportive environment, results in more positive outcomes—connoted by the delicate beauty of the orchid—rather than just the absence of pathology (Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011). Thus research should investigate interactions in addition to testing main effects of risk and protective factors.

ETIOLOGIES

The field has made tremendous progress developing etiological models for bipolar disorder, yet a complete explanation remains tantalizingly beyond reach. Part of the challenge is that different models are focusing on different levels of analysis, and initiatives such as the NIH RDoC are seeking to foster synthesis across these different levels of genetic risk, cellular processes, neurophysiological systems, interpersonal interactions, and so forth (Cuthbert, 2005). A second issue, though, is that the DSM definitions of mood disorders are likely to capture heterogeneous groups with distinct etiologies, as experts now recognize for other polygenic conditions such as ADHD, ASD, and schizophrenia (see Youngstrom, Arnold, & Frazier, 2010, for discussion). Thus a single etiological model is probably an impossible goal, but making the connections between different models remains a worthwhile endeavor.

Genetics

Bipolar disorder has long been known as one of the most heritable major mental illnesses, with heritability estimates of 80% and higher; yet identification of specific genes has been frustratingly slow and prone to replication failures (Mick & Faraone, 2009; Smoller & Finn, 2003). Recent genome-wide association studies in adults find that many genes each contribute small amounts of risk for bipolar disorder (Wellcome Trust Case Control Consortium, 2007). Several genes that have accumulated some evidence tend to also be candidate genes for depression and anxiety (e.g., 5-HTTPLR), psychosis (COMT), ADHD (DRD4), or sleep disturbance (GRK3, CLOCK) (Mick & Faraone, 2009). The "case of the missing heritability," where studies of specific genes account for much less variance than implied by the heritability estimates, is not limited to bipolar disorder; it is endemic to psychiatric genetics (Mick & Faraone, 2009). Possible explanations include that the risk of bipolar disorder may be linked to differences in messenger RNA, not gene-coding DNA, or that large studies are mixing groups with distinct etiologies. Another issue is the poor reliability of clinical diagnoses of bipolar disorder: Most gene studies are relying on registries and clinical diagnoses to describe the phenotype. If the reliability of the phenotype definition hovers around a kappa of .1 to .4 (Regier et al., 2013; Rettew, Lynch, Achenbach, Dumenci, & Ivanova, 2009), then it will be difficult to detect effects. Research to date still strongly confirms that (1) genes play an etiological role in development of bipolar disorder; and (2) the genes identified in PBD are consistent with the genes of interest in adult samples, underscoring the validity of the pediatric diagnoses (Todd & Botteron, 2002).

TABLE 6.2. A Lifespan Developmental Framework for Bipolar Disorder

Epoch	Risk factors	Protective factors	Reciprocal influences	Sequelae	Age-typical issues
Conception	• Genetic factors • Poor maternal prenatal health	• Genetic factors • Good maternal prenatal health			
First trimester					
Second trimester	• Teratogens • Medication exposure	• Maternal diet and exercise			
Third trimester	• Very low birth weight • Prenatal complications • Microbiome	• Beneficial microbiome			
Infancy	• Diet deficient in micronutrients	• Secure attachment • Warm, responsive parenting • Good nutrition (vitamin D, omega-3 fatty acids)			
Toddlerhood	• Difficult temperament	• Warm, consistent parenting	• Mood disrupts parenting → increases conflict → more extreme mood . . .		
Preschool	• Transition into social settings outside home	• High-quality day care			
Elementary school	• Increased conflict in home			• Oppositionality	• High energy and impulsivity

Middle school	• Selecting more deviant peers • Puberty • More directly involved in conflicts	• Dominance and assertiveness may increase popularity (or provoke backlash)	• More conflicts with peers and family • Gender influencing peer relations	• Peer rejection	• Increased depressive symptoms • Risk of overweight
High school	• Sleep dysregulation • Weight gain as side effect of medication • Adolescent phase shift in circadian cycle • Increased androgen levels • Drug experimentation	• Positive social interactions • Academic attainment	• Overweight and poor sleep have positive feedback loop: Poor ghrelin and leptin levels → more eating, obesity → sleep apnea and poor sleep quality → disrupted ghrelin levels . . .	• Overweight + mood dysregulation + low self-esteem → eating disorder • Impulsivity → greater risk of addiction → precocious sexual activity	• Accumulated risk factors for suicidal ideation, behaviors
Early adulthood	• Possible developmental delay in emotion regulation centers (below) • Learned helplessness and hopelessness • Circadian rhythms	• Work: Entrains circadian rhythms (getting up, going to job), provides financial and social support • Normative myelination of emotion regulation circuits	• Greater independence = less structure • Diet (affecting mood and energy, influencing diet . . .)	• Potential downward drift: unemployment, teen pregnancy, other "snares"	
Middle adulthood	• Neurological "kindling" • Allostatic load: substance use, overweight, stress due to work and relational challenges	• Decreasing androgens	• Synaptic "kindling" • Neurological change due to substance use and trauma exposure	• Unmarried or divorced • Underemployed or unemployed	• More depression • Less mania and mixed mood features
Late life	• Cumulative nerve damage • Menopause	• Hormonal changes		• Premature death: heart disease, cancer, accident, suicide	• Accelerated memory loss • Depression • Increased suicide risk

Neurobiological Factors

The neurobiological factors involved in PBD overlap with the systems implicated in depression, schizophrenia, and ADHD. Neurotransmitters of interest include serotonin, dopamine, and (more recently) glutamate (Goodwin & Jamison, 2007). The atypical antipsychotics, which have large effect sizes for the reduction of acute mania, have dopaminergic mechanisms of action (Nandagopal, DelBello, & Kowatch, 2009). Dysregulation of the hypothalamic–pituitary–adrenocortical axis is linked to bipolar disorder, as it is to unipolar depression. There also is evidence for hormonal involvement, including probable androgen effects on mania (Ozcan & Banoglu, 2003), and other endocrinological processes in depression (Cyranowski et al., 2000).

Clinical observers and researchers have long considered bipolar disorder an affective disorder first and foremost, although it also involves disruptions in cognition, sleep, and energy. Consistent with the emphasis on emotional processes, the strongest evidence focuses on emotion regulation systems as being central to the development and progression of bipolar disorder (Strakowski et al., 2012). Specifically, multiple studies find that the amygdala's size and activation in response to emotional stimuli change in bipolar disorder (Chen, Suckling, Lennox, Ooi, & Bullmore, 2011). Two prefrontal cortical systems are responsible for modulating amygdalar activity: a ventrolateral prefrontal cortical system believed to process external emotional stimuli, such as affective facial expressions and cues of threat, and a ventromedial (orbitofrontal) cortical system believed to be responsible for monitoring internal feeling states. These two systems form feedback loops with the amygdala (Strakowski et al., 2012). Multiple studies now find evidence of decreased activity in the regulatory cortices, along with evidence of decreased connectivity between the amygdala and the emotion regulation regions (Blond, Fredericks, & Blumberg, 2012; Townsend & Altshuler, 2012). These neural tracts appear significantly disrupted in bipolar disorder, based on increased white matter hyperintensities in magnetic resonance imaging and higher fractional anisotropy in diffusion tensor imaging studies. A consensus model is emerging: In bipolar disorder, the amygdala appears to be more sensitive to emotional cues, and the cortical structures responsible for modulating fear and anger responses from amygdalar outputs are less connected and perhaps weaker. This creates a propensity for more extreme emotion responses, and for more dysregulation and shifting between mood states—leading to the mixed mood presentations and instability (Strakowski et al., 2012).

Changes in amygdala size and increases in tract disruption are correlated with length of illness, suggesting that successive episodes further damage and disrupt these affective circuits; however, this remains to be confirmed by prospective longitudinal imaging studies with strong designs (Blond et al., 2012; Townsend & Altshuler, 2012). There are fewer studies comparing persons with bipolar disorder to individuals with other conditions (such as ADHD or schizophrenia) instead of healthy controls, but the available evidence indicates that the disruptions of these two affect regulation systems are larger in bipolar disorder than in other conditions (Frazier et al., 2008; Whalley et al., 2012). It is not clear yet how much these differences represent diathesis versus results of illness, and some of the differences observed in adults with bipolar disorder may prove to be results of failure to follow normal adolescent development of these regions, rather than a deficit in preadolescent neurocognitive systems (Strakowski et al., 2012). Evidence suggests that these changes are less likely to be due to medication exposure than had been feared, as medication exposure tends to be associated with normalization of development and decreases in differences versus healthy controls (Hafeman et al., 2012). Overall, the available evidence reinforces the idea that bipolar disorder has a profound neurodevelopmental component.

Psychosocial Factors

Psychosocial factors also play an important role in bipolar disorder, although they have been less studied until recently. As mentioned above, increased conflict in the family and higher expressed negative emotion are tied to earlier age of onset, faster recurrence, and poorer response to treatment in pediatric samples (Geller et al., 2008; Keenan-Miller, Peris, Axelson, Kowatch, & Miklowitz, 2012) as well as adult samples (e.g., Hooley & Hiller, 2001). Although parental mood problems are difficult to disentangle from shared genetic effects between parent and child, such problems are associated with less parental monitoring, engagement, or control (Goodman & Gotlib, 1999). These are likely to exacerbate any underlying diathesis for mood disorder in the youth, although this remains to be demonstrated specifically in bipolar samples. Parental mood dysregulation is also likely to involve modeling of poor emotion

regulation and maladaptive metaemotion (Gottman, Katz, & Hooven, 1996), as well as contributing to higher amounts of stress within the family (Rudolph et al., 2000). Poor emotion regulation in the parent and child also increases the risk of abuse, and trauma and abuse are correlated with greater risk of developing syndromal bipolar disorder (Post & Leverich, 2006). There are hints that sexual abuse may particularly heighten the risk for general mood dysregulation in youth and for bipolar II in particular (Garno, Goldberg, Ramirez, & Ritzler, 2005), but this is partially confounded with the higher rate of sexual abuse among females, who also show higher rates of depression and bipolar II.

Familial Factors

Familial risk of bipolar disorder is well established, but it involves multiple different mechanisms. The genetic and interpersonal elements of familial risk were reviewed above. Familial risk involves other processes, too. One is diet. Choices about food (as well as family exercise patterns) play major roles in childhood obesity and shifts in pubertal onset, as well as influencing mood. There may also be important effects of micronutrients, such as vitamin D and omega-3 fatty acid, whose presence depends on family dietary patterns (Rucklidge & Kaplan, 2013). A more speculative but intriguing possibility is that the "microbiome," or differences in the microbes that live symbiotically in our bodies, may often cluster in families. Variations in the microbiome are showing large effects on obesity (Smith et al., 2013) and immune functioning (Maynard, Elson, Hatton, & Weaver, 2012), suggesting that the microbiome could be a candidate for explaining some of the heritability missing between the family-level and genetic-level estimates. The family is also where many of the environmental and cultural effects described next cluster.

Environmental/Cultural Factors

Culture is one of the most important determinants of diet, and thus it has indirect effects on risk of bipolar disorder through micronutrient consumption, risk of obesity, and the other processes described above. Culture also changes attitudes toward substance use, moderating the exposure of the youth to both opportunities to use substances and potential interpersonal conflict. Culture is associated with differences in attitudes toward women, as well as risk of abuse; in addition, it powerfully affects beliefs about the causes of emotional and behavioral problems, as well as attitudes toward disclosure and treatment seeking (Hinshaw, 2004). Stigma toward mental illness appears present across all cultures, but the degree of this stigma and how it affects behavior are culture-bound (Hinshaw, 2006). There also are mesosystem factors that shape the environment and impinge on the family, such as poverty and exposure to violence in neighborhoods; these also moderate risk of developing internalizing and externalizing problems (Rutter, 2000), and thus are likely to alter risk for bipolar disorder specifically.

More subtly, environmental factors influencing the development of bipolar disorder could include such factors as electricity and changes in ambient lighting. Artificial lighting has considerably changed sleep patterns, and television and the Internet further intrude on our sleep. These electronic influences may be contributing to secular trends in the rise of obesity, as well as to sleep-related impairments in executive function and emotion regulation, and thus plausibly to bipolar disorder (Harvey, 2009). These hypotheses have additional indirect support from clinical interventions that focus on reducing electronic stimulation and improving sleep hygiene (Fristad et al., 2009; Hlastala & Frank, 2006), as well as strong support from chronotherapy trials in adults (Goodwin & Jamison, 2007). Finally, social media on the Internet may create a combustible accelerant to any spark of mood dysregulation, given the way that impulsive statements and pictures can get broadcast widely and cannot be deleted.

CURRENT ISSUES

As the chapter to this point has made clear, there are numerous current issues pertaining to PBD. However, with the recent revision of the DSM nosology, three topics seem notably salient: (1) clarifying diagnostic boundaries with conditions that share features or underlying dimensions; (2) improving assessment to increase the reliability and validity of the evidence base; and (3) improving treatment options, particularly for the bipolar spectrum diagnoses.

Diagnostic Boundaries

As discussed above in the "Dimensional Approaches" section, it is not clear whether bipolar disorder constitutes a "natural category" that is qualitatively different

from other disorders or from the absence of pathology. Several studies suggest that many of the core aspects of bipolar disorder—such as the symptoms of depression or mania, or deficits in impulse control and executive function—are likely to be continua. As others have noted, imposing categorical definitions on phenomena that vary in degree rather than type is a recipe for artificial comorbidity. The regions of the underlying dimension could be claimed by multiple categorical definitions, much as high negative affect defines an area of functioning that is part of anxiety disorders as well as unipolar and bipolar mood disorders (Clark & Watson, 1991).

There also are specific dyads of diagnoses that are important to clarifying the diagnostic boundaries of bipolar disorder. Should these prove to be natural categories or taxa, then research should refine the criteria and guide differential diagnosis. If the substrates are dimensional, or a mixture of categories and continua, then research will help chart the fundamental shared systems and processes, similar to the guiding vision of the RDoC and other dimensional approaches.

Many of the key boundary issues have been discussed in the "Comorbidity" section. Some additional boundaries that will be vital to probe include the differentiation of cyclothymic disorder from BP-NOS/OS-BRD (Van Meter et al., 2012). Inconsistency about lumping these together makes it difficult to compare research samples and contributes to uncertainty about definitions of diatheses, episode length, and other major aspects of phenomenology. Future research also needs to clarify whether cyclothymia is best conceptualized as a temperament, a prodrome, an acute mood disorder in its own right, or a personality disorder (along the lines of an Axis II diagnosis in the DSM-IV nosology) (Parker et al., 2012; Van Meter et al., 2012). In a related vein, there has long been debate about the amount of overlap or connection between borderline personality disorder and bipolar disorder in adults. Personality disorders do not magically appear at one's 18th birthday. They have roots in adolescence, and aspects of them may have antecedents in even earlier biology and experience (Shiner, Tellegen, & Masten, 2001; see Shiner & Tackett, Chapter 18, this volume). Some are beginning to speculate that the BP-NOS/OS-BRD presentations associated with persistent emotion dysregulation may in fact be the pediatric precursors of what would be diagnosed as borderline personality disorder in adults (Zimmerman, Ruggero, Chelminski, & Young, 2010). Finally, the addition of the DMDD diagnosis in DSM-5 creates a new boundary condition that will need to be mapped carefully in distinction to cyclothymic disorder, as well as other depressive and disruptive behavior disorders (Axelson, Birmaher, Findling, et al., 2011).

Improving Assessment and Diagnostic Accuracy

Reliability is a necessary condition for measurements to have validity. Our understanding of PBD languished for decades because researchers and clinicians did not even consider the diagnosis or measure relevant traits, as shown by the fact that only 1% of the epidemiological studies in youth included data about bipolar spectrum disorders (Van Meter, Moreira, & Youngstrom, 2011). Now that the concept of PBD has been popularized, there has been a sharp rise in attention and in rates of diagnoses, but they are too often based on the use of unstructured clinical interviews (with an average kappa of < .10 when compared to semistructured diagnoses of bipolar disorders; Rettew et al., 2009) or of rating scales and definitions that are untested or have shown poor specificity to bipolar disorder (such as the various permutations of CBCL scales; Diler et al., 2009). Inconsistency and imprecision in the definitions of disorders, as well as the definitions of phenomena such as mixed mood features or "rapid cycling" versus mood instability (Youngstrom, 2009), also impede progress. First, samples of "bipolar" cases often include a large portion of cases not actually on the bipolar spectrum, consistent with fears about overdiagnosis of PBD. Second, there is ambiguity about the subtyping within bipolar samples, which complicates identification of meaningful differences in trajectory and treatment response. Third, many actual cases of PBD go undiagnosed, or they are misdiagnosed as something else. As reviewed above, longitudinal data suggest that perhaps a third of cases of adolescent depression ultimately follow a bipolar course; bipolar disorders are also frequently misdiagnosed as conduct problems or psychosis, especially in minority groups. Systematic evaluation of hypomanic symptoms, lifetime history of mania or hypomania, and family history of bipolar disorder would all rapidly, incrementally improve our classifications. The current definitions of disorders are imperfect, and it is likely that many cases with homogeneous clinical presentations will have distinct etiologies. However, improving the accuracy of our assessment and achieving greater consistency in diagnosis are crucial next steps. Upgrading clinical training to include the current data

about prevalence of bipolar spectrum disorders and to teach evidence-based assessment strategies will accelerate progress here (Youngstrom, Freeman, & Jenkins, 2009).

Improving Treatment Options

Although treatment is outside the scope of this chapter and this volume, treatment research also is informative about longitudinal course and underlying mechanisms. There is a troublesome mismatch between the current knowledge base and the epidemiology of PBD. Most treatment research has concentrated on bipolar I disorder, which represents roughly a quarter of the bipolar spectrum in epidemiological studies (Merikangas & Pato, 2009), and most studies use pharmacological interventions. There is a huge unmet need for investigations of prevention, targeted interventions to delay or prevent progression to full manic or depressive episodes, and approaches that target the environmental moderators of risk. The lack of psychosocial interventions has stunted our understanding of PBD because research has not engaged as deeply and thoughtfully with the less biological aspects of the condition. The relative lack of availability of psychosocial interventions also contributes to "upcoding" of diagnoses or misdiagnosing bipolar spectrum disorders as other conditions. Happily there has been progress in developing psychosocial interventions, so that there are now some "probably efficacious" interventions, and several more that show promise (Fristad & Algorta, 2013).

FUTURE DIRECTIONS

The past decade has seen rapid progress in expanding the evidence base about the validity, developmental course, and underlying mechanisms involved in PBD. There are several major conceptual themes that would be profitable areas for investigation. We assume that research into genetic and neurocognitive functioning will continue to advance incrementally yet swiftly. We focus here on three conceptual topics that may offer promise.

Mapping Bipolar Disorder onto the RDoC

As described above, bipolar disorder intersects with most, if not all, of the dimensions articulated so far in the RDoC (Sanislow et al., 2010). We do not advocate an "imperialism of bipolar disorder," in which the definition of bipolar disorder expands to annex all other conditions that share the symptoms or functional dimensions. Instead, we believe that the RDoC vision is likely to prove productive as a way of identifying dimensions that cut across diagnostic categories. This could clarify many instances of what others have called "artifactual" comorbidity (Angold et al., 1999; Caron & Rutter, 1991).

Despite the obvious connections with RDoC dimensions, bipolar disorder also will present some constructive challenges for the RDoC approach. These include the current lack of a good animal model for mania, which hinders integration of some basic science work with human clinical studies. Full understanding of bipolar disorder will require advances in the developmental aspects of the RDoC. Bipolar disorder also is likely to be characterized by instability and fluctuations, rather than simple mean differences in RDoC dimensions, requiring the development of models that look at differences in variance or other measures of within-person change rather than traditional main-effects models testing group means.

Integrating Models of Affective Temperament with Developmental Psychopathology

Several different models of affective temperament have been developed in adults, and they have garnered evidence of validity as correlates of both mood diagnoses and some biological variables (and even genes) of interest (e.g., Akiskal et al., 2005; Cloninger, Svrakic, & Przybeck, 1993). However, they have not been examined in much depth in pediatric samples, and they have not assimilated a developmental psychopathology framework. Affective temperaments are presumed to be stable and are treated as static variables, whereas a developmental psychopathology model would strive to connect models of temperament in infancy and early childhood with temperament and personality constructs in adolescence and adulthood (Cicchetti, 2010). The developmental psychopathology approach also offers sophisticated transactional models of biological and environmental effects, which are only beginning to be applied to adult affective temperament. Better integration of these approaches will help clarify the developmental continuities, as well as improving our understanding of what constitutes temperamental diathesis versus early-stage illness. Cyclothymic temperament has rarely been studied in youth, but clearly overlaps with aspects

of difficult temperament, for example. Cyclothymia also illustrates the ambiguity about conceptualizing a constellation of behaviors as "temperament" versus more chronic disorder. A variety of measures have accrued evidence of cross-sectional validity (Akiskal et al., 2005; Cloninger et al., 1993; Luby, Svrakic, McCallum, Przybeck, & Cloninger, 1999; Rothbart & Posner, 2006). The next steps will be to collect "linking samples" that pair "adult" and "youth" temperament measures in the same participants, to establish when the same underlying construct has been given different labels by each test author; and then to repeat administration prospectively, to be able to track what changes occur in the course of typical development versus presaging poorer outcomes.

Reconceptualizing Bipolar Disorder as a Systemic and Developmental Disorder

Our last proposal for a future direction is the most ambitious: We believe that the future of bipolar disorder lies in reconceptualizing it as a systemic condition that needs to be understood developmentally in order to be prevented or managed appropriately. We look to the changes in thinking about heart disease as a source of inspiration and ideas. Like heart disease, bipolar disorder does not involve a single organ. Instead, the risk of illness is tied to immune functioning, diet, sleep, exercise, metabolic functioning, and social and interpersonal factors such as stress. These same factors are showing complex yet compelling associations with heart disease. A simplistic analogy would be to conceptualize bipolar disorder as a "systemic brain disease," with severe mood episodes as being analogous to heart attacks. Unpacking this analogy reveals a wide variety of parallels and shared mechanisms, including strong correspondence between how each episode/attack can cause lasting harm even if an individual survives it. The symmetry also implies that a holistic approach to conceptualization and treatment is likely to have greatest impact. Early identification and intervention may shift to management of risk factors and mechanisms, much as prevention of heart disease involves management of blood pressure, glycemic index, and weight in order to delay or prevent the first infarct. Such a reconceptualization opens up a broad range of topics for psychological study and intervention. It also offers a structure to organize the rapid influx of data that is revolutionizing our understanding of PBD.

CHAPTER 7

Suicidal and Nonsuicidal Self-Injurious Thoughts and Behaviors

CHRISTINE B. CHA
MATTHEW K. NOCK

Self-injurious thoughts and behaviors (SITBs) represent a collection of maladaptive and life-threatening outcomes. SITBs range from nonsuicidal self-injury (NSSI; e.g., self-cutting) to suicide. Suicide is particularly concerning, as it is the second leading cause of death among adolescents and young adults, resulting in approximately 4,600 deaths per year (Centers for Disease Control and Prevention [CDC], 2013). Discussion of SITBs is especially timely in light of the newly proposed diagnoses of NSSI and suicidal behavior disorder that appear in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association [APA], 2013) as "Conditions for Further Study" in Section III.

This chapter reviews current knowledge about these perplexing behavior problems. Existing work should be viewed as preliminary steps toward better understanding SITBs. Although recent years have yielded nearly a doubling of research articles on the topic of SITBs (Cardinal, 2008), they have been disproportionately understudied. There still remain key challenges that the field is only now beginning to address. These include defining and classifying SITBs consistently, establishing reliable prevalence rates of all SITBs, empirically testing the interaction of relevant risk factors, and accurately predicting future SITB risk. Through these ongoing efforts, both current and future research can be expected to produce more precise and generalizable findings.

HISTORICAL CONTEXT

History reveals much societal rejection and stigma surrounding SITBs such as suicide and NSSI. Most past records pertain to suicide, and later ones include NSSI. A glance at specific historical views may help explain the relatively delayed emergence of this field of research.

Suicide has been a particularly controversial topic, as the inherent life-or-death nature of this phenomenon has challenged many philosophical, religious, and legal principles. Records go back to the classical period. While Stoics and Epicureans expressed tolerance for suicide during this time, some Greek philosophers, such as Aristotle and Pythagoras, viewed suicide attempt as a cowardly act (Minois, 1999; Williams, 1997).

Early religious authorities, including those of the Roman Catholic, Jewish, and Islamic faiths, also condemned suicide as a sin; in many cases, these condemnations directly influenced the law's treatment of suicide as a crime. For example, England in the Middle

Ages considered "self-murder" as an offense against nature, God, and the King (Williams, 1997). During this time, the moral and legal acceptability of suicide was critically dependent on *why* a person killed him- or herself. A suicide death with the *felo de se* (i.e., "felon of himself") verdict implied that the individual exercised free will when killing him- or herself and was therefore fully responsible for this crime. A suicide death with the *non compos mentis* verdict pointed toward an "unsound mind" as the primary reason for suicide. In the 16th and 17th centuries, people's interpretations of an unsound mind were based on either religion (e.g., the devil had taken possession of a person's soul) or psychology (e.g., the person had a mental illness). These deterministic explanations assumed that the individual could not be held accountable for his or her actions and therefore did not warrant posthumous punishment.

The gradual decrease in *felo de se* cases over time reflects the eventual decriminalization of suicide in many countries. The American colonies began decriminalizing suicide in the early 1700s. The term "suicide" began replacing the term "self-murder." After years of endorsing public shaming of suicide, France had its last documented case of *felo de se* in 1791 (Williams, 1997). Other European countries such as Germany, the Netherlands, and Norway decriminalized suicide between the mid-18th and 19th centuries (Neeleman, 1996). Although it was known for its rigid policies against suicide (Williams, 1997), even England witnessed fewer *felo de se* verdicts, more *non compos mentis* verdicts, and removal of religious and secular punishments for suicide by the late 1800s. However, it was not until 1961 that Parliament passed the Suicide Act, officially decriminalizing suicide in England and Wales (Neeleman, 1996).

This gradual process of decriminalization across time has led to a drastic shift in the way society now approaches the topic of suicide. In many countries, suicide has become a problem to understand and solve. Moving away from earlier religious interpretations of *non compos mentis*, research in psychology, medicine, and sociology has begun to elucidate ways in which to prevent (rather than punish) suicide. More precise measurement and greater attention toward suicide may also help explain some suicide trends over time. For example, increased efforts to classify a death appropriately as suicide may have contributed to the documented rise in adolescent and young adult suicide rates during the 1950s (Jamison, 1999). Other factors contributing to this increase may have included earlier and increased access to lethal means, younger age of alcohol use, and increased psychopathology among youth.

Up until the 20th century, most historical accounts relevant to NSSI pertained to culturally sanctioned body modification. Such body modification methods were deemed acceptable by societies at different points in time for various purposes: physical healing (e.g., trephination, in which holes were cut into the skull to relieve epilepsy), spirituality (e.g., spilling human blood to anoint Aztec idols), and social orderliness (e.g., scarification of pubescent girls among the Tiv people) (Favazza, 1987).

Documentation and commentary on culturally deviant NSSI behavior, as defined in the current chapter, emerged in the psychoanalytic literature toward the mid-1900s. These early interpretations considered NSSI to represent an unconscious attack on bodily parts representing genitalia (Menninger, 1938). Researchers and clinicians began profiling "wrist cutters" as typically young, intelligent, attractive women with particular psychological characteristics (e.g., history of drug use, lack of connection with others, feelings of relief from cutting) (e.g., Graff & Mallin, 1967). The greater number of publications and more frequent media coverage on the topic of NSSI have elucidated a more nuanced understanding of this behavior (Miller & Brock, 2010), as detailed in this chapter.

There are multiple reasons why nonsuicidal SITBs have not been as closely documented or discussed as suicidal SITBs until recently. First, behaviors such as NSSI are inherently less life-threatening and less visible than suicide. Second, until the mid-1990s NSSI was considered unworthy of research (see Favazza, 2009). This was likely a reflection of social norms, which deemed this to be an inappropriate behavior to acknowledge as a society. NSSI was similarly considered unworthy of treatment, as earlier efforts to establish a formal diagnosis around this behavior (e.g., "deliberate self-harm syndrome," "repetitive self-mutilation syndrome"; Favazza & Rosenthal, 1993; Kahan & Pattison, 1984) did not gain recognition in the DSM until its most recent edition (APA, 2013). Third, NSSI rates may have in fact been lower in the past, so that there was less to study until now. This possibility is based on a reportedly large increase in self-injury rates between 1985 and 1995 (Hawton, Fagg, Simkin, Bale, & Bond, 1997). This increase should be interpreted with caution, however, as those statistics include both suicidal and nonsuicidal self-injurious behaviors (Heath, Schaub, Holly, & Nixon, 2009).

The growing dialogue and concern around SITBs are prompting more research and treatment efforts now more than ever before. The quality of research is becoming increasingly refined and specific to subpopulations, such as youth. The remainder of this chapter discusses the current state of SITB research among this particularly vulnerable age group.

CLASSIFICATION AND DEFINITIONS

In order to study SITBs properly, a necessary first step is to classify and define them. There are currently two groups of SITBs: nonsuicidal and suicidal. Nonsuicidal SITBs include NSSI thoughts, NSSI behavior, and NSSI as a disorder (as newly defined by DSM-5). Suicidal SITBs include suicide ideation, suicide plan, suicide gestures, suicide attempt, suicide death, and suicidal behavior disorder (as defined by DSM-5).

NSSI Thoughts and Behavior

The term "NSSI thoughts" refers to serious consideration of or desire to engage in NSSI. These thoughts typically occur when a person is alone and experiencing negative thoughts (e.g., anger, aversive memory), and last for 1–30 minutes (Nock, Prinstein, & Sterba, 2009). Adolescents who think about NSSI experience these thoughts approximately five times per week.

"NSSI behavior" is defined as direct and deliberate physical harm to oneself in the absence of intent to die. Although most persons who injure themselves report little or no pain, NSSI episodes typically result in moderate to severe tissue damage (Nock & Prinstein, 2005; Whitlock, Muehlenkamp, & Eckenrode, 2008). Common forms of NSSI among youth include cutting, scratching, burning, biting, and hitting parts of the body (e.g., Laye-Gindhu & Schonert-Reichl, 2005; Lloyd-Richardson, Perrine, Dierker, & Kelley, 2007; Nock & Prinstein, 2004). Most adolescents use more than one method for NSSI, and perceive the behavior to induce more pain when a greater number of methods are used (e.g., Nock, Joiner, Gordon, Lloyd-Richardson, & Prinstein, 2006). Commonly targeted areas of the body for NSSI include hands, wrists, arms, and thighs (Whitlock, Eckenrode, & Silverman, 2006). The current definition of NSSI excludes culturally sanctioned self-injury (e.g., tattoos, body piercings), less severe forms of self-injury (e.g., picking wounds, nail biting), and other risky behaviors (e.g., gambling, substance misuse).

Youth report engaging in NSSI more frequently than adults do. Compared to young adults, who most often report engaging in NSSI fewer than 10 times in their lives (Whitlock et al., 2008), adolescents report doing so as frequently as 50 times a year or 1–2 times each week (Nock & Prinstein, 2004; Nock, Prinstein, & Sterba, 2009). Although substance and alcohol use is more common among self-injuring adolescents, the NSSI episodes themselves typically occur when adolescents are not using drugs or alcohol (Nock & Prinstein, 2005).

NSSI as a Disorder

Starting with DSM-5, the field now recognizes NSSI as potentially a disorder warranting its own clinical diagnosis (APA, 2013; see Table 7.1). The core feature of the newly proposed NSSI diagnosis is repeated NSSI behavior with clear intent to self-injure. Specifically, a person must have engaged in NSSI for at least 5 days over 1 year (Criterion A). This 5-day minimum is intended to capture those who intentionally engage in this behavior repeatedly, rather than those engaging only in isolated instances of experimentation. There must also be a clear lack of suicidal intent during the NSSI episodes. This may be determined either through explicit indication (e.g., patient report) or repetitively engaging in a behavior that the patient believes will not cause death. This feature emphasizes the similar but critically distinct phenomenology of suicidal and nonsuicidal behaviors.

The proposed criteria for NSSI as a disorder also require engaging in NSSI with the expectation that this behavior will serve a specific function (Criterion B). Examples of such expectations are that NSSI will reduce internal distress or increase pleasure. Moreover, there are three possible associated features of NSSI disorder (Criterion C): immediate psychological precipitants (e.g., tension, anger, distress); preoccupation with NSSI that is hard to resist; and frequent thoughts about self-injuring even in the absence of action. At least one out of these three must be endorsed to meet this criterion.

To be clear, self-injurious behaviors outlined by DSM-5 do not include those that are sanctioned by society or by the person's culture or religion (Criterion D). They also do not include those that are restricted to nail biting or picking at wounds. These DSM-5 exclusion criteria reflect the same ones discussed in this chapter for NSSI behavior.

TABLE 7.1. DSM-5 Proposed Criteria for Nonsuicidal Self-Injury

A. In the last year, the individual has, on 5 or more days, engaged in intentional self-inflicted damage to the surface of his or her body of a sort likely to induce bleeding, bruising, or pain (e.g., cutting, burning, stabbing, hitting, excessive rubbing), with the expectation that the injury will lead to only minor or moderate physical harm (i.e., there is no suicidal intent).
   Note: The absence of suicidal intent has either been stated by the individual or can be inferred by the individual's repeated engagement in a behavior that the individual knows, or has learned, is not likely to result in death.
B. The individual engages in the self-injurious behavior with one or more of the following expectations:
   1. To obtain relief from a negative feeling or cognitive state.
   2. To resolve an interpersonal difficulty.
   3. To induce a positive feeling state.
      Note: The desired relief or response is experienced during or shortly after the self-injury, and the individual may display patterns of behavior suggesting a dependence on repeatedly engaging in it.
C. The intentional self-injury is associated with at least one of the following:
   1. Interpersonal difficulties or negative feelings or thoughts, such as depression, anxiety, tension, anger, generalized distress, or self-criticism, occurring in the period immediately prior to the self-injurious act.
   2. Prior to engaging in the act, a period of preoccupation with the intended behavior that is difficult to control.
   3. Thinking about self-injury that occurs frequently, even when it is not acted upon.
D. The behavior is not socially sanctioned (e.g., body piercing, tattooing, part of a religious or cultural ritual) and is not restricted to picking a scab or nail biting.
E. The behavior or its consequences cause clinically significant distress or interference in interpersonal, academic, or other important areas of functioning.
F. The behavior does not occur exclusively during psychotic episodes, delirium, substance intoxication, or substance withdrawal. In individuals with a neurodevelopmental disorder, the behavior is not part of a pattern of repetitive stereotypies. The behavior is not better explained by another mental disorder or medical condition (e.g., psychotic disorder, autism spectrum disorder, intellectual disability, Lesch-Nyhan syndrome, stereotypic movement disorder with self-injury, trichotillomania [hair-pulling disorder], excoriation [skin-picking] disorder).

Note. Reprinted with permission from *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (p. 803). Copyright 2013 by the American Psychiatric Association.

To count toward a diagnosis of NSSI as a disorder, NSSI or its effects must also result in functional impairment (Criterion E)—that is, clinically important distress or disturbance in interpersonal, academic, or other major areas of functioning.

The final criterion details what NSSI as a disorder excludes (Criterion F). In order to ensure clear intent to self-injure, the definition does not include self-injury in the context of delirium, substance intoxication/withdrawal, or psychosis. NSSI as a disorder also excludes other forms of self-injurious behaviors, including those that are compulsive, impulsive, and stereotypic in nature (Favazza, 1987). These include repetitive stereotypies or those accounted for by other mental disorders (e.g., trichotillomania, various developmental disabilities, Lesch–Nyhan syndrome).

Proponents of this new diagnostic category argue that the NSSI diagnosis will enhance both research and practice (e.g., Muehlenkamp, 2005). In research, this proposed DSM-5 disorder will more clearly delineate nonsuicidal from suicidal behaviors, whose definitions have been often confused and treated interchangeably in past research (see below). These definitional inconsistencies have yielded unreliable prevalence rates and etiological findings. Definitional clarifications will facilitate accurate advancement in knowledge about both nonsuicidal and suicidal behaviors, potentially informing policy change (Shaffer & Jacobson, 2009).

Clinically, the establishment of NSSI as a disorder may improve the quality of assessments and individual patient care. A current problem is that individuals who engage in NSSI are often assumed to be suicidal. As many as 88% of adolescent inpatients report having their nonsuicidal cutting behaviors misinterpreted as suicide attempts (Kumar, Pepe, & Steer, 2004), potentially leading to unnecessarily restrictive and burdensome management methods such as inpatient hospitalization (Shaffer & Jacobson, 2009). Clinicians often

misdiagnose self-injuring patients with borderline personality disorder (BPD)—a label that is especially concerning when applied to children and adolescents, whose personalities are still developing (APA, 2000; Wilkinson & Goodyer, 2011). The criteria for NSSI as a disorder allow patients who self-injure to be represented as a distinct group, calling attention to the development of treatment approaches more specific to this concerning behavior outcome (Shaffer & Jacobson, 2009).

Notably, the introduction of NSSI as a disorder does not resolve the aforementioned problem of misdiagnosis. Those participating in the DSM-5 field trials found poor interrater reliability for the NSSI diagnosis (Freedman et al., 2013), highlighting the need for further study. The inclusion of NSSI in Section III of DSM-5 allows recognition of this new diagnosis, but does not permit reimbursement for existing treatment approaches.

Not all individuals support DSM-5 inclusion of NSSI as a disorder. Leading up to the DSM-5 release, concerned opponents of this diagnosis argued that the current state of research provides inadequate justification for diagnostic criteria (see DeLeo, 2011). Adding to this concern is the degree of stigma that may come to surround this mental disorder label—stigma perceived by both the general public and the diagnosed individuals themselves. Opponents claimed that the cost of such stigma may outweigh the benefits of establishing this diagnosis. Placement of NSSI in Section III of DSM-5, which highlights the novel and still tentative nature of this diagnosis, potentially tempers these opposing views.

Suicide Ideation and Plan

"Suicidal ideation" refers to serious thoughts about suicide or desire to kill oneself. One study with community-based adolescents revealed that those with suicidal ideation typically experience a suicidal thought once per week (Nock, Prinstein, & Sterba, 2009). Compared to NSSI thoughts, suicidal ideation typically lasts longer and leads to self-injurious actions less frequently. Beyond thoughts, a "suicide plan" is defined as serious consideration of how one would kill oneself. Making suicide plans and taking preparatory actions toward suicide (e.g., accessing lethal means) are more strongly associated with suicidal intent and behaviors than is suicidal ideation among adolescents (Pettit et al., 2009).

Suicide Gesture

"Suicide gestures" are defined as actions people take to make others believe that they want to kill themselves when they in fact have no intention of doing so. A gesture is also sometimes referred to as a "suicide threat." Adolescents typically report doing this in the presence of peers, and those who engage in this behavior do so an average of four or five times during their lives (Nock, Holmberg, Photos, & Michel, 2007). Notably, suicide gestures are less reliably reported behaviors across time, since adolescents who initially report this outcome often do not report it again when assessed later.

Suicide Attempt

A "suicide attempt" is defined as engagement in a self-injurious behavior with at least some (i.e., nonzero) intent to die. More than half of first-time suicide attempts are planned in advance, leaving approximately 40% who make unplanned attempts (Nock et al., 2013). Compared to adults, adolescents tend to use more over-the-counter medicines, are less certain of the lethality of their attempt, and are more frequently hospitalized for attempts (Parellada et al., 2008). Other methods of attempt include using firearms, hanging/suffocation, and jumping.

Suicide Death

"Suicide death," alternatively referred to in this chapter simply as "suicide," is a fatality that directly results from a suicide attempt. One common misperception is that the outcomes of suicide attempt and death are analogous with one another. Those who die by suicide represent only a portion of those who attempt it, and reflect distinct prevalence rates and sociodemographic characteristics (Moskos, Achilles, & Gray, 2004). Researchers have called for development of distinct prevention approaches and outcome measures for suicide attempt and death.

Suicidal Behavior Disorder

DSM-5 (APA, 2013) includes a new suicidal behavior disorder diagnosis (see Table 7.2). Its core feature is having engaged in a behavior within the past 24 months that was intended to end the patient's life (Criterion A). Although it is possible for a person to have engaged in NSSI separately, the self-injurious behavior required

TABLE 7.2. DSM-5 Proposed Criteria for Suicidal Behavior Disorder

A. Within the last 24 months, the individual has made a suicide attempt.
Note: A suicide attempt is a self-initiated sequence of behaviors by an individual who, at the time of initiation, expected that the set of actions would lead to his or her own death. The "time of initiation" is the time when a behavior took place that involved applying the method.)

B. The act does not meet criteria for nonsuicidal self-injury—that is, it does not involve self-injury directed to the surface of the body undertaken to induce relief from a negative feeling/cognitive state or to achieve a positive mood state.

C. The diagnosis is not applied to suicidal ideation or to preparatory acts.

D. The act was not initiated during a state of delirium or confusion.

E. The act was not undertaken solely for a political or religious objective.

Specify if:
Current: Not more than 12 months since the last attempt.
In early remission: 12–24 months since the last attempt.

Note. Reprinted with permission from *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (p. 801). Copyright 2013 by the American Psychiatric Association.

to qualify for the suicidal behavior disorder diagnosis *must* be paired with suicidal intent (Criterion B). Behavior counting toward this diagnosis does not include suicidal ideation or preparatory acts (Criterion C); nor can it have been initiated in a confused or delirious state (Criterion D) or solely for religious or political reasons (Criterion E). Along with NSSI disorder, suicidal behavior disorder has been placed in Section III of DSM-5 as a new diagnosis requiring further study.

DEFINITIONAL ISSUES

Research and clinical work on SITBs have been plagued by the use of vague and inconsistent terms and definitions for the aforementioned behaviors, preventing reliable comparison of NSSI-related findings across studies. The most concerning point of confusion is that between nonsuicidal and suicidal SITBs. Researchers in the United States have equated the term "deliberate self-harm" with NSSI, whereas those in the United Kingdom have used this and other terms (e.g., "parasuicide") to include *both* nonsuicidal and suicidal SITBs (e.g., Claes & Vandereycken, 2007). Some studies that have examined NSSI behavior, as defined in this chapter, have used other terms such as "self-mutilation," "cutting," "self-harm," or "self-inflicted injury." Researchers have called for a resolution of such inconsistencies (e.g., Nock & Kessler, 2006), and the field has increasingly used the definition and term "NSSI" as presented above (Nock, 2010).

Some findings regarding suicidal SITBs must be interpreted with caution due to definitional issues. For example, respondents themselves may have varied interpretations of the term "suicide attempt." According to one large-scale study, more than 40% of people who reported making a suicide attempt subsequently indicated that they actually did not want to die as a result of their behavior (Nock & Kessler, 2006). Also worth considering is the distinction between suicide attempt resulting in physical injury, and an attempt from which a person does not sustain injury because he or she changed their mind or was stopped (i.e., an aborted or interrupted suicide attempt; Barber, Marzuk, Leon, & Portera, 1998; Posner et al., 2011). Researchers are making greater efforts to establish consistency in suicidal SITB nomenclature and definitions, for the benefit of both researchers and clinicians.

EPIDEMIOLOGY

Prevalence/Incidence

Not surprisingly, more adolescents think about NSSI than engage in it. One community-based study reports that 42% of high school students experience NSSI ideation, and 9% experience more severe NSSI preoccupation (Laye-Gindhu & Schonert-Reichl, 2005). This is higher than the rate of NSSI thoughts reported among young adults (16.7%; Martin, Bureau, Cloutier, & Lafontaine, 2011).

Adolescents more often engage in self-injurious acts in the absence (vs. presence) of suicidal intent. Lifetime NSSI prevalence rates for community-based adolescents typically range between 15 and 20% (see Heath et al., 2009). Although cross-national work is limited, initial studies demonstrate relatively consistent prevalence rates across countries including the United States, the Netherlands, and Italy (Giletta, Scholte, Engels, Ciairano, & Prinstein, 2012). Factors such as NSSI definitions and assessment methods contribute to the range of prevalence rates. For example, research studies that include less severe forms of NSSI behavior (e.g., nail biting, wound picking) or use a checklist self-report to measure NSSI are more likely to report higher prevalence. Rates in clinical settings are much higher and have an even wider range: Some 40–82% of adolescent patients report past-year NSSI (e.g., Guertin, Lloyd-Richardson, Spirito, Donaldson, & Boergers, 2001; Nock & Prinstein, 2004). Adolescents generally report NSSI much more often than adults, who report 5.9% lifetime prevalence in the community, and approximately 30% in clinical settings (Jacobson, Muehlenkamp, Miller, & Turner, 2008; Klonsky, 2011). Researchers have begun to explore the prevalence of NSSI as a disorder as well, reporting 6.7% of community-based Swedish adolescents meeting the proposed criteria (Zetterqvist, Lundh, Dahlström, & Svedin, 2013).

Adolescents are most likely to engage in suicidal ideation out of all suicidal SITBs. A nationally representative U.S. study (the National Comorbidity Study Replication—Adolescent Supplement, or NCS-A) recently reported that 12.1% of community-based adolescents have seriously thought about committing suicide at least once in their lives (Nock et al., 2013). Other epidemiological studies of youth report somewhat higher U.S. (19.8–24.0%) and cross-national (21.7–37.9%) lifetime rates of suicidal ideation (Nock, Borges, Bromet, Cha, et al., 2008).

Suicide plan and attempt occur less frequently. Four percent of community-based adolescents have made a suicide plan, and that the same proportion has attempted suicide (Nock et al., 2013). Some epidemiological studies report slightly higher lifetime prevalence rates of suicide attempt among youth, ranging from 3.1 to 9.7% (Evans, Hawton, Rodham, & Deeks, 2005; Nock, Borges, Bromet, Cha, et al., 2008). As expected, hospital-based studies also report higher rates (e.g., 47.5% past-year history; Prinstein et al., 2008). Rates of these suicidal SITBs tend to be higher among youth than among adults. In fact, adults' lifetime prevalence rates for suicidal ideation, plan, and attempt are lower than the corresponding 12-month prevalence rates for adolescents (see Nock, Borges, Bromet, Cha, et al., 2008). One potential explanation is that suicidal behaviors may be increasing over time. Another, more likely explanation is that adults underreport their history of suicidal SITBs.

Suicide gestures also seem to be prevalent among youth. More than 20% of community-based adolescents and young adults (12–19 years) have engaged in a suicide gesture at least once in their lives (Nock et al., 2007). The same study reported relatively high past-year and past-month prevalence rates of suicide gestures (12.8% and 2.1%, respectively). Adult samples, by contrast, report a 1.9% rate of gestures (Nock & Kessler, 2006).

Adding to the gravity of SITBs, suicide is a common cause of death among youth. In the United States, data from the CDC (2013) reveal that an average of 3.9–4.5 suicide deaths per 100,000 children and adolescents occur each year between 2005 and 2010. The most common forms of suicide death in recent years have been suffocation (47.8%), firearms (38.8%), and poisoning (6.3%). When broken down further, the same data set reveals higher incidence rates among older adolescents (15–19 years; 6.7–7.5 per 100,000) than among children and younger adolescents (10–14 years; 0.9–1.3 per 100,000). Cross-national data on youth (<15 years) are comparable and range from 0.04 (England and Wales) through 1.32 (Russian Federation) per 100,000 (DeLeo & Evans, 2003). Rates of suicide death increase into adulthood, with an average incidence rate of 12.7–14.3 per 100,000 youth and adults (10–85+ years; CDC, 2013).

Sex Differences

There remains some debate about sex differences related to NSSI. Earlier profiles and theories about NSSI depict individuals who self-injure as typically being female (e.g., Graff & Mallin, 1967). Research with adolescents often supports this claim, with many studies reporting that girls are at least twice as likely to engage in NSSI as boys (e.g., Laye-Gindhu & Schonert-Reichl, 2005; Nixon, Cloutier, & Jansson, 2008). This is also the case for NSSI as a diagnosis (Zetterqvist et al., 2013). One possible explanation for this sex difference is the particularly strong effect of late-stage puberty among female adolescents, which increases risk of nonsuicidal and suicidal SITBs among girls even

after age and grade level are controlled for (Patton et al., 2007). This is especially the case for self-laceration and self-poisoning. The link between late-stage puberty and SITBs is at least in part explained by depressive symptoms, substance use, and sexual activity reported by girls during this time period. These may serve as stressful precipitants of SITBs. Another possible explanation is that all of these outcomes result from earlier social stressors, such as childhood sexual abuse or family dysfunction.

A notable inconsistency across empirical studies that may directly affect findings related to sex differences is in the definition of NSSI behavior. Some researchers argue that most samples demonstrating sex differences include a broader range of NSSI methods, such as medication abuse in the absence of suicidal intent (Heath et al., 2009). Other studies have found sex differences among more common NSSI methods, such that girls are more likely to cut themselves, whereas boys tend to hit themselves (Laye-Gindhu & Schonert-Reichl, 2005). Such inconsistent findings similarly exist for adults, perhaps due to the same NSSI method-related issues (see Muehlenkamp, 2005).

Research on sex differences for suicidal SITBs yields more conclusive findings. Nock and colleagues (2013) demonstrated that adolescent girls experience suicidal ideation nearly twice as often as boys, and attempt suicide nearly three times as often. This sex difference persists into adulthood (Kessler, Berglund, Borges, Nock, & Wang, 2005), and generalizes to Mexico, China, and European countries (Borges, Benjet, Medina-Mora, Orozco, & Nock, 2007; Hesketh, Ding, & Jenkins, 2002; Kokkevi, Rotsika, Arapaki, & Richardson, 2012). There is no sex difference when it comes to which adolescents who experience suicidal ideation go on to make a suicide plan (Nock et al., 2013).

Although girls are more likely to attempt suicide, boys are more likely to die by suicide. Boys have a higher incidence of suicide death in the United States and in most countries (see Berman, Jobes, & Silverman, 2007). Recent CDC data reflect similar patterns, with rates of 6.1–6.9 per 100,000 for boys and 1.5–2.0 per 100,000 for girls (CDC, 2013). Most cross-national data on youth and adult suicide deaths feature at least a 2:1 male–female ratio. An exception is China, whose selected rural and urban regions feature more frequent female suicide deaths (see Nock, Borges, Bromet, Cha, et al., 2008; World Health Organization [WHO], 2013). India had also been an exception, as it demonstrated a 1.3:1 male–female ratio (see Nock, Borges, Bromet, Cha, et al., 2008), but more recent data on India reveal a more typical 1:0.6 ratio of suicide deaths (WHO, 2013). Several factors may account for these differences, such as more frequent accessibility and selection of lethal means, greater degree of aggressiveness, and stronger suicidal intent characterizing male suicide deaths (Beautrais, 2002).

Sociodemographic Correlates

Both nonsuicidal and suicidal SITBs occur at different rates among those of different races and ethnicities. Broadly speaking, community-based European American youth are more likely to engage in moderate/severe NSSI than are African American or Asian American youth (Lloyd-Richardson et al., 2007). Similar patterns emerge for nonfatal suicidal SITBs (Nock et al., 2013). Native Americans represent an especially concerning demographic group, as they are more likely to die by suicide than any other racial group during adolescence (Nock, Borges, Bromet, Cha, et al., 2008). This is confirmed by recent suicide incidence rates among Native American adolescent boys (14.6 per 100,000) that are twice as high as those for girls (7.2 per 100,000) (CDC, 2013). Data on Hispanic/Latino youth are mixed, with some studies reporting more risk of SITBs (e.g., CDC, 2012) and some reporting less risk (e.g., Evans et al., 2005; Muehlenkamp, Cowles, & Gutierrez, 2010).

Aside from specific racial or ethnic characteristics, minority group status may be especially important to consider. That is, the racial/ethnic composition of an individual's immediate surroundings may be just as important to consider as the race/ethnicity of that individual. An example of this is Neeleman and Wessely's (1999) examination of suicide deaths throughout London. Afro-Caribbean and Asian individuals throughout London were found to be at greater risk of suicide, *unless* they were from geographical areas with greater populations of Afro-Caribbean and Asian individuals.

Further emphasizing the impact of minority group status, research has begun to suggest that SITBs present differently among sexual minority youth. College-based studies have found that students who identify their sexual orientation as homosexual, bisexual, or questioning are more likely to engage in NSSI (Gratz, 2006; Whitlock et al., 2006). Similar results were found for community-based adolescents endorsing nonheterosexual orientation (homosexual, bisexual, other; Deliberto & Nock, 2008). Sexual minority youth also are at greater risk of suicidal ideation and attempt (Fer-

gusson, Horwood, & Beautrais, 1999), as they report suicidal ideation nearly twice as often as heterosexual youth, and suicide attempt more than three times as often (Marshal et al., 2011).

There are mixed findings on the connection between nonsuicidal SITBs and socioeconomic status (SES) as defined by education or family income. On the one hand, some studies have found no differences in NSSI rates from sociodemographically distinct settings (e.g., urban vs. suburban high school comparison; Ross & Heath, 2002). And those examining variation within a single sample have not detected associations between NSSI and adolescents' SES or parental education (e.g., Laye-Gindhu & Schonert-Reichl, 2005; Lloyd-Richardson et al., 2007). On the other hand, some studies have reported alarmingly high rates of NSSI among privileged youth, with more than a third of a community-based sample reporting NSSI behaviors (Yates, Tracy, & Luthar, 2008). This unexpected prominence of NSSI may be due to achievement-oriented pressures combined with reduced familial closeness among this sociodemographic group (Luthar & Becker, 2002).

Although lower SES is associated with adults' suicidal SITBs, including suicide death (Qin, Agerbo, & Mortensen, 2003), it remains questionable whether education and income have an impact on suicide rates among youth. A recent cross-national study demonstrated that lower educational attainment increases risk of suicide-related outcomes in adulthood, but *decreases* such risk among youth (4–19 years) (Nock et al., 2012). This is especially the case in low- and middle-income countries. Regarding the other SES factor of family income, economic hardship during childhood can be among the array of early adversities that increase the likelihood of early-onset suicidal behaviors, especially in high-income countries (Bruffaerts et al., 2010). Revisiting the impact of minority status, it may be especially important to consider the role of individuals' SES in comparison to the surrounding economic climate.

AGE OF ONSET, COURSE, AND PROGNOSIS

Age of Onset

Nonsuicidal SITBs typically begin at adolescence. Researchers consistently report NSSI onset at early adolescence, with ages ranging from 12 to 15 years (Heath et al., 2009; Klonsky, 2007). Studies have also reported earlier instances of self-injury (presence of suicidal intent unknown) as young as eight years old (Hawton, Fagg, & Simkin, 1996). NSSI behavior may emerge during adolescence for a variety of reasons, such as learning about NSSI from peers, generating the idea of NSSI themselves, or learning about it from the media (Deliberto & Nock, 2008).

Suicidal SITBs also tend to emerge during adolescence. Risk of first-time suicidal ideation increases around the age of 12 years, peaks at approximately 16 years, and remains heightened into young adulthood (Nock, Borges, Bromet, Cha, et al., 2008). Though suicidal ideation and attempt have been recorded at ages as early as 4–5 years (see Pfeffer, 1997; Tishler, Reiss, & Rhodes, 2007), some researchers question young children's capacity for suicidal intent. Specifically, prepubertal youth may not yet understand the finality of death or be able to accurately predict the lethal consequences of their actions (Cuddy-Casey & Orvaschel, 1997; Pfeffer, 1997). Risk factors such as parental absence or childhood maltreatment may help account for earlier onsets of suicide-related outcomes (Bolger, Downey, Walker, & Steininger, 1989; Roy, 2004). Suicide gesture and attempt have similar ages of onset—approximately 13–14 years (Nock et al., 2007).

Course and Recurrence

Clinicians and experts in the field have noted that NSSI behavior typically persists for 10–15 years (e.g., Favazza, 1998). More than half of self-injuring adolescents stop engaging in NSSI and other self-injuring behaviors on their own by adulthood (Moran et al., 2012). Most adolescents engaging in NSSI report wanting to stop this behavior for the following reasons (listed in descending order by popularity): judgment that it is an unhealthy behavior, unwanted attention from others, scarring, feelings of shame, and family/friends' distress over their NSSI (Deliberto & Nock, 2008).

The prognosis of NSSI is concerning, since it increases risk of engaging in suicidal SITBs. At least among clinical samples, adolescents engage in NSSI for longer periods of time, use a greater number of methods, and report less pain from NSSI are more likely to attempt suicide in the future (Nock et al., 2006; Zlotnick, Donaldson, Spirito, & Pearlstein, 1997). NSSI is a strong indicator of later suicide attempt, to the point where it can predict attempt above and beyond history of suicidal behaviors (Wilkinson, Kelvin, Roberts, Dubicka, & Goodyer, 2011). Notably, among a minority

of self-injuring individuals, NSSI may prevent both suicidal ideation and attempt by providing an immediate, alternative coping mechanism (*antisuicide model*; Klonsky, 2007; Suyemoto, 1998).

Adolescent suicidal ideation typically persists and increases the likelihood of future psychopathology and suicidal behaviors. Approximately half of youth with suicide ideation continue experiencing such thoughts after their initial age of onset (Kessler et al., 2012). An important factor to consider is exactly *when* people first think about suicide. Earlier onset of suicidal ideation is associated with greater persistence of this outcome (Kessler et al., 2012), further highlighting the importance of interviewing early. Persistence of such thoughts is particularly cyclical for clinical patients. After an initial decline in adolescents' suicidal ideation following hospital discharge, such thoughts typically reemerge 9 and 18 months later (Prinstein et al., 2008). Factors that hinder remission of suicidal ideation include higher adolescent-reported depressive symptoms, higher NSSI frequency, and lower parent-reported externalizing symptoms.

According to several longitudinal studies, suicidal ideation can increase risk of subsequent psychopathology. Adolescent ideators may experience increased depressive, substance use, and anxiety disorders (Fergusson, Horwood, Ridder, & Beautrais, 2005; Garrison, Addy, Jackson, McKeown, & Waller, 1991). They also experience a decline in general behavioral and emotional functioning, interpersonal relationships, and self-esteem, and an increase in psychopathology, following ideation onset (Reinherz et al., 1995). It is possible that suicidal ideation has only a short-term impact on psychopathology, however, since examination of longer-term effects yields mixed findings (e.g., Dhossche, Ferdinand, van der Ende, Hofstra, & Verhulst, 2002).

Most notably, suicidal ideation increases the likelihood of more severe outcomes, such as suicide plan or attempt. In addition to the *presence* of suicidal ideation, *specific changes* in thoughts over time predict suicide attempt (Prinstein et al., 2008). That is, the rate at which suicidal thoughts subside or recur is strongly linked with subsequent suicide attempts. Suicidal ideation can also help predict when a person will act on their thoughts. Cross-national findings consistently report that 60% of adults with suicidal ideation transition to suicide plans or attempts within the first year of experiencing suicidal thoughts (Nock, Borges, Bromet, Alonso, et al., 2008). Future work needs to test whether this is the case among adolescents.

Although by definition a suicide gesture occurs *without* intent to kill oneself, it can still have implications for subsequent suicidal behaviors. One prospective study demonstrated that adolescent inpatients with histories of suicide gestures/threats are more likely to attempt suicide following discharge (Prinstein et al., 2008). More specific details regarding the duration or course of other nonsuicidal SITBs (e.g., the transition from NSSI thoughts to NSSI) remain unknown.

In addition to its immediately life-threatening nature, a suicide attempt indicates a poor longer-term prognosis. Adolescents who attempt suicide often reattempt. Nearly a quarter of adolescent attempters reattempt within 1 year, and nearly half reattempt within 10 years (Grøholt & Ekeberg, 2009; Hultén et al., 2001). This relationship between past and future suicidal behaviors has been rigorously tested and found to exist even when accounting for individuals' hopelessness and related psychopathology (e.g., Joiner et al., 2009). Suicide researchers have attributed reattempt to heightened aggression, cognitive sensitization (i.e., heightened accessibility to suicidal thoughts), and opponent processes (i.e., enhanced calming, pain-relieving effects from attempts) (Joiner, 2005; Stein, Apter, Ratzoni, Har-Even, & Avidan, 1998). As expected, a suicide attempt can also result in suicide death. Specifically, one-third of adolescents who die by suicide have made at least one prior suicide attempt (Marttunen, Aro, & Lönnqvist, 1992).

DIAGNOSTIC CORRELATES

With the exception of the proposed DSM-5 diagnoses of NSSI and suicidal behavior disorder, SITBs are not clinical diagnoses. Instead, the present section reviews common co-occurrences between SITBs and existing DSM-IV diagnoses. As such, these represent diagnostic correlates rather than comorbidities.

Nonsuicidal SITBs

Researchers and clinicians often observe NSSI behavior co-occurring with borderline personality disorder (BPD). This is not surprising, as the DSM-IV-TR criteria for BPD include NSSI as a symptom (APA, 2000). Approximately 50–60% of self-injuring adolescent

inpatients meet criteria for BPD (Ferrara, Terrinoni, & Williams, 2012; Nock et al., 2006). In some cases, NSSI may mark the emergence of BPD characteristics during adolescence. Crowell and colleagues (2012) found that self-injuring adolescents exhibited more BPD symptoms (e.g., avoidant behavior, self-damaging impulsivity) than depressed and noninjuring adolescents did. The combination of NSSI with suicidal behaviors may further increase co-occurrence or severity of BPD symptoms (Muehlenkamp, Ertelt, Miller, & Claes, 2011).

Despite their frequent co-occurrence, NSSI and BPD can be viewed as clinically distinct entities. Initial studies have directly compared BPD with the proposed diagnosis of NSSI as a disorder among adolescents and adults, and have found that self-injuring patients without BPD demonstrate a comparable (if not greater) degree of functional impairment as those diagnosed with BPD (Glenn & Klonsky, 2013; Selby, Bender, Gordon, Nock, & Joiner, 2012). NSSI behavior is also linked to other personality disorders, such as avoidant and paranoid personality disorders (Nock et al., 2006).

Adolescents who engage in NSSI behavior also meet criteria for several other disorders. Generally, the diagnoses most commonly co-occurring with NSSI behavior include substance use disorder, major depressive disorder, and impulse-control disorders. Adolescent inpatients with a history of NSSI most typically meet criteria for substance use disorder (59.6%), conduct disorder (49.4%), oppositional defiant disorder (44.9%), major depressive disorder (41.6%), and posttraumatic stress disorder (PTSD; 23.6%; Nock et al., 2006).

Suicidal SITBs

Approximately 90% of adolescents who have experienced suicide ideation or made suicide plans have a lifetime history of at least one DSM-IV diagnosis (Nock et al., 2013). The most commonly endorsed group of mental disorders among those with suicide ideation is depression/dysthymia (56.8%). Other commonly co-occurring diagnoses include disruptive behavior disorders (intermittent explosive disorder, 29.4%; oppositional defiant disorder, 34.4%; conduct disorder, 20.0%), substance use disorders (illicit drug abuse, 27.4%; alcohol abuse, 18.4%), and specific phobia (36.8%). Adolescents with ideation who go on to make plans are also especially likely to have a history of depression/dysthymia.

The connection between depression and suicide attempt varies depending on age. Among adults, depression appears to be associated with suicide attempts only through its strong and more direct association with suicidal ideation and plans (Nock, Hwang, Sampson, & Kessler, 2010). When controlling for suicidal ideation, depression no longer predicts suicide attempts; instead, disorders characterized by agitation and poor impulse control predict which of these adults will make a suicide attempt (Nock, Hwang, et al., 2009; Nock et al., 2010). Among adolescents, however, depression is more specifically and closely associated with suicide attempts (Nock et al., 2013). Specifically, a wide array of diagnoses ranging from depression/dysthymia to impulse-control disorders (e.g., intermittent explosive disorder, conduct disorder) and other diagnoses (e.g., eating disorders, attention-deficit/hyperactivity disorder) predict which adolescents experiencing suicidal ideation will also attempt suicide.

THEORETICAL FRAMEWORK

There are numerous theoretical approaches to both studying and treating SITBs. The theories most relevant to today's research and evidence-based practice are reviewed below. These theoretical frameworks could be applied to both youth and adults.

Theories on NSSI Behavior

Several theories explain what combinations of long-term factors contribute to NSSI behavior, such as why people choose this behavior over others and what maintains the behavior once it starts. Theories with the broadest of scopes (e.g., Nock, 2010) propose that temporally distal vulnerability factors at least partially account for NSSI behavior. These distal vulnerability factors could be environmental (e.g., childhood sexual abuse, dysfunctional family dynamics), biological (e.g., increased physiological response to stress, decreased prefrontal cortex activity), or psychological (e.g., poor communication skills, high self-criticism) in nature. Nock's (2010) integrative model assumes that a *combination* of these vulnerabilities is what increases the likelihood of NSSI. For example, rather than focusing solely on one environmental stressor (parental criticism) or psychological vulnerability (self-critical thinking), Wedig and Nock (2007) demonstrated that

the *interaction* of these two factors is especially predictive of SITBs, including NSSI. That is, parental criticism is especially deleterious for adolescents who think very self-critically. This model also assumes that temporally proximal risk factors (e.g., physiological hyperarousal to stress) further increase the likelihood of NSSI behavior.

A similar developmental multivariate view is Linehan's (1993) *biosocial theory*, which proposes that distal vulnerabilities increase risk of both NSSI and suicidal behaviors. Linehan specifies that "affective instability" (i.e., the tendency for emotional reactions to be more immediate, more intense, and longer-lasting) is a core biological deficit among self-injurious individuals—particularly those with BPD. It is not affective instability alone, but instead its combination with an "invalidating environment" (e.g., childhood trauma, family dysfunction), that increases SITB risk. Supporting studies have demonstrated that the quality of emotion regulation plays a central role in explaining adolescent NSSI behavior, and that this psychological risk factor mediates the effects of family- and peer-based stressors (e.g., Adrian, Zeman, Erdley, Lisa, & Sim, 2011).

Several theories focus more on the outcome of NSSI, and argue why at-risk adolescents specifically choose NSSI over other maladaptive behaviors have been proposed (Nock, 2009b). According to the *pragmatic hypothesis*, individuals choose NSSI because it can serve its purpose especially quickly and effectively. This behavior typically does not require much time, money, or energy, and is thereby a lower-maintenance activity than other maladaptive behaviors, such as substance use or binge eating. Another possibility is the *implicit identification hypothesis*, in which people may choose NSSI because they identify with their perceived concept as "self-injurers." This is supported by recent studies in which self-injuring adolescents demonstrated stronger implicit associations between the concepts of "self" and "cutting" on a behavioral task (i.e., *Implicit Association Test*; Nock & Banaji, 2007). In addition, the *self-punishment hypothesis* proposes that people may choose NSSI because it represents self-directed abuse, similar to what they have received in the past. Studies indeed demonstrate a history of parental criticism (Wedig & Nock, 2007) and child maltreatment (e.g., Glassman, Weierich, Hooley, Deliberto, & Nock, 2007) among adolescents who self-injure.

The following hypotheses describe how immediate interpersonal functioning may affect the decision to choose NSSI over other maladaptive behaviors. The *social signaling hypothesis* (Nock, 2008) states that NSSI is a means to communicate with others when more normative (i.e., less intense) efforts to communicate have failed. NSSI may in fact be an especially effective signal because of its clearly harmful and costly nature. Adolescents who self-injure demonstrate poor verbal communication skills (e.g., Hilt, Cha, & Nolen-Hoeksema, 2008), highlighting circumstances in which NSSI behavior may indeed serve a social function. Finally, according to the *social learning hypothesis*, some individuals engage in NSSI as a result of observing this behavior in others. This hypothesis is applicable to nearly half of self-injuring adolescents, who report learning about NSSI through their peers or media sources (Deliberto & Nock, 2008).

Once individuals select NSSI as a maladaptive behavior, the *four-function model of NSSI* (Nock & Prinstein, 2004) helps explain what maintains it over time. The primary assumption of this theory is that NSSI persists because of events immediately preceding and following an NSSI episode. According to this theory, there are two dimensions along which individuals are motivated to continue engaging in NSSI. The first dimension pertains to whether adolescents self-injure for reasons pertaining to themselves (i.e., automatic) or others (i.e., social). The second dimension indicates whether the NSSI behavior is followed by removal of an aversive stimulus (i.e., negative reinforcement) or presentation of a favorable stimulus (i.e., positive reinforcement). Combined, these dimensions categorize four motivations for NSSI. These categories are automatic negative reinforcement (e.g., to stop feeling bad about oneself), automatic positive reinforcement (e.g., to feel something even if it is pain), social negative reinforcement (e.g., to avoid doing something unpleasant with others), and social positive reinforcement (e.g., to communicate with others).

Although studies support the validity of all four functions, automatic negative reinforcement has received the greatest amount of empirical support. This is likely due to the fact that it is the most commonly endorsed function among both adolescents (Nixon, Cloutier, & Aggarwal, 2002; Nock & Prinstein, 2004) and adults (Brown, Comtois, & Linehan, 2002). Self-injuring adolescents reporting automatic negative reinforcement exhibit more internal distress, such as greater hopelessness, emotion reactivity, and physiological response to stressors (Nock & Mendes, 2008; Nock & Prinstein, 2005). Such evidence points toward a particularly aver-

sive automatic experience from which one may be motivated to escape. As expected, adolescents endorsing automatic positive reinforcement report greater anhedonia, inactivity, and PTSD symptoms such as psychic numbness (Nock & Prinstein, 2005; Weierich & Nock, 2008). In support of the social functions, adolescents who endorse social negative or positive reinforcement report greater history of peer victimization and socially oriented perfectionism, as well as an improvement in relationships with their fathers following NSSI episodes (Hilt et al., 2008; Hilt, Nock, Lloyd-Richardson, & Prinstein, 2008; Nock & Prinstein, 2005). These social functions are more often endorsed by adolescents than by adults (Lloyd-Richardson, Nock, & Prinstein, 2009). And unlike adults, adolescents who self-injure are just as likely to endorse social functions as automatic functions (Lloyd-Richardson et al., 2007). The reason for heightened youth-endorsed social functions remains unclear. One possibility is that during this developmental period, adolescents' sense of identity is strongly determined by their perception of social norms (see Heilbron & Prinstein, 2008).

Several other functions for NSSI have been proposed (see Klonsky, 2007; Suyemoto, 1998). For example, alternative functions include boundary definition (i.e., marking skin as a means of separating oneself from the environment), sensation seeking, sexually oriented gratification or punishment, or reduction of suicidal urges (i.e., an antisuicide function). There is less clarity surrounding these functions, and subsequently less evidence in support of them. This may in part be due to overextension of the term "function" to mean "general purpose or reason" for NSSI (Lloyd-Richardson et al., 2009). In the current chapter, this term strictly refers to antecedents and consequences of NSSI behavior.

Theories on Suicidal Behavior

Theories point toward a wide range of influences on suicide attempt and death. Some, for example, focus on societal impact. The broadest theoretical framework is Durkheim's (1897/1951) sociological theory on suicide, which classifies suicide death according to the relationship between society and an individual. According to Durkheim's theory, there are four classes of suicide. *Egoistic* suicide occurs when an individual fails to integrate him- or herself with society (e.g., an orphan, a social outcast). *Altruistic* suicide occurs when an individual kills him- or herself for the perceived greater good of society (e.g., a suicide bomber). *Fatalistic* suicide occurs when society overregulates an individual (e.g., a criminal on probation). Finally, *anomic* suicide occurs when there is a sudden change in relationship between an individual and society (e.g., a person who experiences a drastic decrease in income/class).

Other theoretical explanations for suicide attempt and death focus on the individual, and point toward core psychological characteristics. Beck's (1967) *cognitive theory* emphasizes how negative thoughts pertaining to oneself, the world, and the future contribute to depression and potentially suicidal ideation. Beck has also proposed that an activated suicide schema affects information-processing biases (e.g., memory, interpretation, attentional biases) and increases hopeless and suicidal thinking. The role of hopelessness has received a substantial amount of support, as it is a powerful psychological risk factor for suicidal thoughts and behaviors (e.g., Beck, Steer, Kovacs, & Garrison, 1985; Smith, Alloy, & Abramson, 2006). More recently, Wenzel and Beck (2008) have explained how hopelessness may contribute to not only suicidal thoughts, but also behaviors. Specifically, hopelessness may interact with attentional fixation (i.e., narrowing of focus on suicide as a viable option to circumstances) to exacerbate suicidal thoughts and the likelihood of attempting suicide.

Other psychological theories focus on the comparable but distinct construct of entrapment. For example, Baumeister's (1990) *escape theory* similarly proposes that the intolerability of negative automatic thoughts and the resultant need for escape lead to suicidal thoughts and behaviors. Williams's (1997) *cry of pain* model further clarifies that individuals who attempt suicide do not wish to die, but instead wish to escape from feeling an overwhelming sense of defeat.

Other theories integrate both the sociological and psychological perspectives. The most strongly supported integrative theory is Joiner's (2005) *interpersonal-psychological theory* of suicidal behavior, which argues that there are three key elements contributing to suicide attempt and death. First, individuals must believe that they impose a burden on significant figures in their lives (i.e., perceived burdensomeness). Studies have indeed demonstrated that perceived burdensomeness is associated with suicidal ideation, intent, and lethality of suicide attempt method (Joiner et al., 2002, 2009), and that such risk factors have an even stronger effect than hopelessness (Van Orden, Lynam, Hollar, & Joiner, 2006). The second element of this model is that individuals must experience a lack of belongingness and connectivity to those around them (i.e., thwarted

belongingness). Similar to perceived burdensomeness, thwarted belongingness is associated with suicidal ideation (Joiner et al., 2009). Finally, such individuals must also have the capacity and courage to attempt suicide (i.e., capability for suicide). This last element also provides a theoretical explanation for why those who engage in NSSI are at greater risk of suicide attempts and death: Repeated self-injurious behaviors habituate an individual and reduce fear toward suicidal behaviors. To further support this final piece, studies have demonstrated that those who experience or engage in habituating behaviors (e.g., substance abuse, body modifications, surgery, violence, early life trauma) are more likely to attempt suicide (Joiner, 2005).

ETIOLOGICAL FINDINGS

While the aforementioned theories drive some research on SITB etiology, much of this field has identified risk factors for SITB outside any theoretical context. In order to integrate these distinct findings, below we organize risk factors according to three domains: biological, environmental, and psychological risk factors. We review each domain and highlight risk factors specific to a particular type of SITB when possible.

Biological Factors

Several decades of research suggest that suicidal behavior is associated with dysregulation of the neurobiological stress response system, specifically the hypothalamic–pituitary–adrenocortical (HPA) axis (Braquehais, Picouto, Casas, & Sher, 2012). Several studies have demonstrated this in the suicidal youth population by examining elevated plasma cortisol, a byproduct of the HPA axis, using multiple methods such as dexamethasone suppression tests (Pfeffer, Stokes, & Shindledecker, 1991) and examination of a continuous 24-hour cortisol secretory period (Dahl et al., 1991). Cortisol levels are associated not only with whether a patient is suicidal, but also with the severity of suicide-related outcomes (Pfeffer et al., 1991). Importantly, not all studies demonstrate hypercortisolism. Some have found *lower* levels of cortisol among individuals at risk of suicide (e.g., first-degree relatives of individuals who died by suicide; McGirr et al., 2010). Similarly, HPA axis dysfunction among youth engaging in NSSI has been shown to yield both hyper- and hypocortisolism (Barrocas et al., 2011; Kaess et al., 2012).

Closely linked to the activation of the HPA axis is the endogenous opioid system, which features abnormalities linked especially with NSSI behaviors. Individuals who engage in NSSI demonstrate lowered levels of beta-endorphins and met-enkephalins, which are endogenous opioid peptides associated with stress-induced analgesia and pain perception (e.g., Stanley et al., 2010). This is consistent with the fact that persons who self-injure demonstrate increased tolerance and lowered sensitivity to physical pain (Bohus et al., 2000; Claes, Vandereycken, & Vertommen, 2006). Some researchers propose that opioids facilitate perception not only of physical pain, but also of social pain in both animals and human beings (MacDonald & Leary, 2005). This is consistent with the notion that NSSI behavior can serve both intra- and interpersonal functions (Nock & Prinstein, 2004). Animal studies offer evidence suggesting that self-injurious behaviors (e.g., self-directed biting) serve a potentially regulatory function and increase beta-endorphin levels (Tiefenbacher et al., 2003).

Deficient serotonergic neurotransmission also has been associated with NSSI and suicidal behaviors. Individuals engaging in either form of self-injurious behavior typically exhibit serotonergic hypofunction (e.g., Herpertz, Sass, & Favazza, 1997; Mann, Oquendo, Underwood, & Arango, 1999). Among adolescents, decreased levels of platelet serotonin (5-HT) are related to greater severity of suicidal behaviors (Tyano et al., 2006). Other serotonergic abnormalities among suicidal youth include increased number of 5-HT2A receptors, protein, and messenger RNA expression throughout specific brain regions such as the prefrontal cortex and hippocampus (Pandey et al., 2002). Findings are mixed, as other studies report *reduced* 5-HT2A binding in the frontal cortex of patients who recently attempted suicide (see Desmyter, van Heeringen, & Audenaert, 2011).

Although most research has focused on serotonergic activity, some work suggests that the dopaminergic system may also contribute to suicidal and nonsuicidal self-injurious behaviors. Low levels of dopamine have been linked with self-injury in developmental disorders and Lesch–Nyhan disease (see Sher & Stanley, 2009). Although some studies demonstrate hypofunction of the dopaminergic system among suicidal individuals, it remains unclear whether this is driven by associated depressive symptoms (Mann, 2003).

Some brain structure abnormalities have been linked to SITBs. White matter hyperintensity, for example, is

one of the few structural abnormalities rigorously examined among suicidal youth. The connection between white matter hyperintensities and suicidal thoughts and behaviors depends on the subtype: periventricular hyperintensities (PVHs) versus deep white matter hyperintensities (DWMHs). PVHs exhibit an especially strong link to suicidal thoughts and behaviors, even when researchers control for depression (Ehrlich et al., 2004). DWMHs are also associated with these outcomes when examined in the parietal lobe, but not the frontal lobe (Ehrlich et al., 2003).

At least among adults, another structural marker that may distinguish suicidal from nonsuicidal people is gray matter volume. Research thus far suggests reduced gray matter volume in the frontal lobe of suicidal adults (see Desmyter et al., 2011), even after controlling for depression (Wagner et al., 2011). This needs to be tested among younger populations. Thus far, studies examining depressed adolescents similarly reveal reduced gray matter volume in the frontal lobe (Shad, Muddasani, & Rao, 2012).

Family studies point toward the possibility that there may be some genetic risk factors for SITBs, specifically suicide attempts. One adolescent twin study found that shared genes may account for nearly 50% of the variance in suicide attempts (Glowinski et al., 2001). The pattern of family clustering has been replicated more recently and in larger-scale studies, emphasizing the primary role that genetic factors play in explaining suicide-related outcomes (Tidemalm et al., 2011). This is likely not due to any shared risk of general psychopathology. Studies have shown that when researchers control for family history of psychopathology, adolescent suicide victims have more first-degree relatives who have also attempted suicide than demographically similar nonsuicidal adolescents have (Brent, Bridge, Johnson, & Connolly, 1996). Family clustering of suicidal ideation and attempts has also been found, although these outcomes may also be attributed to shared risk of psychopathology (Brent et al., 1996; Bridge, Brent, Johnson, & Connolly, 1997).

Research on specific genetic risk factors, thus far, has focused on candidate genes implicated in serotonergic and dopaminergic functioning. For example, the short allele of the serotonin transporter promoter gene (5-HTTLPR) is associated with suicidal behaviors and may also be associated with NSSI through its link to emotion dysregulation (Barrocas et al., 2011; Mann et al., 2000). Another potential example is the catechol-*O*-methyltransferase (COMT) gene, which contributes to metabolic functioning of dopamine (Barrocas et al., 2011). This is an area that requires a significant amount of research.

Psychological Factors

Nonsuicidal and suicidal SITBs share several psychological risk factors. Generally, a negative internal experience precedes engagement in SITBs. Negative automatic (i.e., self-oriented) and self-critical thoughts specifically characterize SITBs among children and adolescents (Nock & Kazdin, 2002; Wedig & Nock, 2007). These thoughts may be specifically related to hopelessness (Nock & Kazdin, 2002; Wilkinson et al., 2011), low self-esteem (Lundh, Karim, & Quilisch, 2007; Wedig & Nock, 2007), or body dissatisfaction (e.g., Muehlenkamp & Brausch, 2012). Perfectionism, especially socially prescribed perfectionism (i.e., perception of others' unrealistically high expectations of one's own behavior), may contribute to such negative or self-critical thoughts. This form of perfectionism is more characteristic of self-injurious youth than is self-oriented perfectionism (i.e., self-imposed expectations for oneself that are unrealistically high) (Boergers, Spirito, & Donaldson, 1998; O'Connor, Rasmussen, & Hawton, 2009).

Self-injurious youth are characterized not only by negative emotions, but also by distinctive ways they modulate such emotions. Research studies on NSSI and distress tolerance have used physiological measures to demonstrate that self-injuring youth exhibit greater skin conductance under stress than non-self-injuring youth do (Nock & Mendes, 2008). This is complemented by the fact that self-injuring individuals who even imagine engaging in NSSI experience a reduction of physiological arousal, indicating that tension reduction potentially reinforces NSSI behavior (Haines, Williams, Brain, & Wilson, 1995). Self-reported emotion regulation and reactivity (i.e., sensitivity) are also associated with NSSI behavior (Gratz, 2006; Nock, Wedig, Holmberg, & Hooley, 2008). Importantly, emotion regulation and reactivity can result in either exceptionally strong or weak emotional experiences. Some self-injurious youth report anhedonia and dissociation to be the driving motivations for NSSI (Gratz, Conrad, & Roemer, 2002; Zlotnick et al., 1996), although these are less common than other motives.

Several cognitive mechanisms may exacerbate these aforementioned psychological risk factors. For example, trying to suppress unwanted thoughts and emotions

can result in a strong rebound effect of such thoughts and emotions. Najmi, Wegner, and Nock (2007) found that this propensity for thought suppression mediated the links between emotion reactivity and NSSI and suicidal ideation among youth. The opposite approach of rumination can also be harmful, since distressed youth with ruminative thinking styles are more likely to engage in NSSI maintained via automatic negative reinforcement than are nonruminative youth (Hilt et al., 2008).

Importantly, a cognitive mechanism that is not in and of itself a risk factor can *still* contribute to SITB risk by interacting with the aforementioned psychological risk factors. An example of this is the fact that poor executive functioning (i.e., problem solving) is unrelated to suicide attempt when examined independently, but can increase the likelihood of an attempt when combined with poor emotion reactivity (Dour, Cha, & Nock, 2011). More distal cognitive mechanisms that increase risk of SITBs are dysfunctional attitudes, negative attributional biases, and overgeneralized autobiographical memory (Arie, Apter, Orbach, Yefet, & Zalzman, 2008; Hankin & Abela, 2011).

The well-known association between impulsiveness and SITBs is tempered by mixed findings of exactly what measure and type of impulsiveness such associations involve. For example, the degree to which adolescents consider themselves to be impulsive (i.e., self-report measure) is more predictive of NSSI than whether or not their actions reflect such impulsiveness (i.e., behavioral measure). Self-reported impulsiveness has been shown to consistently characterize adolescents who engage in NSSI (Janis & Nock, 2008) and potentially suicidal behaviors (O'Connor, Rasmussen, & Hawton, 2012). Within the same sample of adolescents (Janis & Nock, 2008), performance-based measures of behavioral disinhibition and risky decision making were not significantly related to NSSI behavior. One possible reason for this inconsistency is that impulsiveness is related differently to NSSI compared to other SITBs. Behavioral measures of reward-directed impulsiveness have been shown to be associated with other SITBs such as suicide attempts (Horesh, 2001; Mathias et al., 2011). Similar behavioral measures have been used to differentiate adolescents who engage in NSSI who have, versus have not, also attempted suicide (Dougherty et al., 2009). Another likely possibility is that only specific aspects of impulsiveness are related to SITBs. Finally, the behavioral measures used thus far may not accurately capture the type of impulsiveness that influences SITBs in natural settings. As researchers have highlighted in related fields of psychopathology (e.g., attention-deficit/hyperactivity disorder; Barkley, 1991), behavioral or laboratory-based measures of executive functioning have poor ecological validity. This may also be the case in the study of SITBs. In short, this particular area of SITB research requires a more systematic approach of examining the multifaceted risk factor of impulsiveness in relation to NSSI and suicide attempts.

One type of psychological risk factor more specific to NSSI behavior relates to interpersonal functioning. Adolescents who engage in NSSI demonstrate particular impairments in social problem-solving skills, such as selecting an optimal solution to interpersonal conflict (Nock & Mendes, 2008). Self-injuring youth also exhibit poor communication skills; they not only struggle with expressing their own emotions (Gratz, 2006), but also perceive poor communication with their peers (Hilt et al., 2008). Although social problem-solving skills and poor communication have also been demonstrated among suicidal youth (Howard-Pitney, LaFromboise, Basil, September, & Johnson, 1992; Riesch, Jacobson, Sawdey, Anderson, & Henriques, 2008), these risk factors are considered less relevant and are often accounted for by co-occurring depressive symptoms and hopelessness (Boergers et al., 1998; Speckens & Hawton, 2005).

Environmental Factors

The most widely researched long-term environmental risk factor for SITBs is childhood maltreatment, especially childhood sexual abuse. Victims of childhood sexual abuse are more likely to engage in NSSI, suicidal ideation, and suicide attempts during adolescence (Brown, Cohen, Johnson, & Smailes, 1999; Glassman, Weierich, Hooley, Deliberto, & Nock, 2007). It is especially alarming that 29–50% of adolescents who are sexually abused try to kill themselves, and that this association persists even after investigators control for psychological factors such as hopelessness (Martin, Bergen, Richardson, Roeger, & Allison, 2004). It remains unclear whether the effect of sexual abuse is stronger for male versus female victims; some argue that this effect raises suicide risk especially among boys (see Rhodes et al., 2011), and others argue that it raises risk among girls (Bergen, Martin, Richardson, Allison, & Roeger, 2003). One thing that is consistent across all victims is the fact that greater numbers and types

of perpetrators (e.g., family and nonfamily members) increase risk of suicide attempts (Eisenberg, Ackard, & Resnick, 2007). Other forms of childhood maltreatment, such as physical and emotional abuse, can also have a deleterious effect on adolescent SITBs (Beautrais, Joyce, & Mulder, 1996; Brown et al., 1999; Glassman et al., 2007). Some of the aforementioned research demonstrates the impact of neglect as well, although it may have a less direct impact on adolescent outcomes.

Other important risk factors for adolescent SITBs can be found in the immediate environment, such as family and school functioning. "Family functioning" can refer to the quality of relationships either among the family members themselves or with the self-injuring youth directly. For example, family conflict, poor parental care, and poor parental relationships (e.g., parental separation) all increase risk of suicide attempts during adolescence (Brent, Melhem, Donohoe, & Walker, 2009; Wilkinson et al., 2011), which is not otherwise accounted for by parental psychopathology (Beautrais et al., 1996). What has an especially strong impact on NSSI behavior is the quality of relationships between family members and the self-injuring youth, such that family loneliness (i.e., an adolescent's feeling alone when he or she is with the family) rather than general family dysfunction is associated with NSSI (Giletta et al., 2012; Wilkinson et al., 2011). Adolescents' feeling of connectedness with their family members can in fact protect against the otherwise harmful impact of other well-known risk factors, such as childhood sexual abuse (Eisenberg et al., 2007).

The importance of connectedness extends to the school setting, as the degree of integration with peers affects rates of SITBs among youth. Studies have found that adolescents who experience low engagement with the school setting (e.g., having religious convictions that deviate from a Catholic school culture) are more likely to engage in NSSI and attempt suicide (Young, Sweeting, & Ellaway, 2011). Beyond simply being different from others, the lack of peer tolerance in particular increases SITB risk. For example, Borges and colleagues (2011) report that experiencing discrimination in school because of one's heritage predicts which adolescents will engage in NSSI or experience suicidal ideation, whereas basic immigrant status (e.g., U.S.-born vs. non-U.S.-born) does not.

Other risk factors are general peer victimization and bullying among youth. Adolescents who experience peer victimization that is either overt (e.g., physical altercations) or relational (e.g., spreading rumors) are more likely to experience suicidal ideation, attempt, and NSSI behaviors (Giletta et al., 2012; Hilt et al., 2008; Pranjić & Bajraktarević, 2010). Adolescents who are bullied in multiple ways (e.g., sexual jokes, attacks on race/religion, judgments about physical appearance) and through multiple media (e.g., in person, online) are at greater risk of suicide-related outcomes (Hay & Meldrum, 2010; Klomek, Marrocco, Kleinman, Schonfeld, & Gould, 2008). In fact, those who are victims of both in-person bullying and cyberbullying are approximately five times more likely to engage in SITBs than are nonvictims (Schneider, O'Donnell, Stueve, & Coulter, 2012). Interestingly, any involvement in bullying—even as a perpetrator—increases the likelihood of SITBs, especially among girls (Hinduja & Patchin, 2010; Kim, Leventhal, Koh, & Boyce, 2009; Klomek et al., 2008). Peer victimization has not only an immediate but also a long-term impact on SITBs. Both men and women who recall incidents of childhood bullying, even decades after the bullying incidents, are at increased risk of attempting suicide (Klomek et al., 2009; Meltzer, Vostanis, Ford, Bebbington, & Dennis, 2011).

Peer influence serves not only as a source of stress but also as a reward, with the latter being a powerful motivator for SITBs. For example, an adolescent who perceives many friends or close friends to be engaging in NSSI is more likely to engage in this behavior themselves (Prinstein et al., 2010), and nearly 40% of adolescents who self-injure first learn about this behavior from their peers (Deliberto & Nock, 2008). Experimental paradigms have also demonstrated that people use social information to inform their own behavior, even when it is self-injurious or aggressive in nature (Berman & Walley, 2003). This is likely facilitated by the desire for conformity and self-identity that is particularly characteristic of this developmental period (Heilbron & Prinstein, 2008), and it helps explain the "contagion effects" that have been observed in adolescent inpatient units (Rosen & Walsh, 1989). Similar concerns are prompted by the increasing use of the mass media and specifically the Internet as a source of community and validation for self-injuring youth (Whitlock, Lader, & Conterio, 2007). Related work involving suicide deaths also demonstrate a "Werther effect," in which exposure to nonfictional (vs. fictional) portrayals of suicide in the media results in a subsequent increase in suicidal behaviors in the population (Pirkis & Blood, 2001).

Another potential explanation for suicide clusters is "assortative relating." Joiner (2003) suggests that per-

haps "suicide clusters" are preset, as people possessing similar characteristics are already more likely to form relationships with one another. In support of this explanation, Joiner reports that the concurrence of suicide risk is greater in self-selecting roommates than in randomly assigned roommates.

One environmental risk factor particularly notable and specific to suicide is household firearm ownership. This is a risk factor for suicide death across all age groups, and the strongest magnitude of association can be found among youth (5–19 years; Miller, Lippmann, Azrael, & Hemenway, 2007). This relationship is not accounted for by psychopathology or other suicide risk factors among either youth or adults (Miller et al., 2007; Miller, Barber, Azrael, Hemenway, & Molnar, 2009).

FUTURE DIRECTIONS

Although impressive progress has been made in the understanding of suicidal and nonsuicidal SITBs in recent years, there is a great deal of important work to be done in the years to come. Several recent papers have outlined key unanswered questions in the study of suicide and self-injury among youth (Brent, 2011; Nock, 2009a), the most important of which are highlighted below.

What Is Self-Harm?

As described in this chapter, researchers and clinicians have achieved increasing precision and consistency in the classification systems and definitions used in this area in recent years. However, further improvements are needed. For instance, the field lacks a method for clearly distinguishing between suicide ideation and suicide planning. That is, if a person thinks about killing him- or herself and imagines jumping off a bridge, does that constitute having a plan? If the person thinks of a method, but has not thought of a time and place to commit suicide, does the person have a plan? We know that having a plan increases the risk of suicide attempt, but it would be valuable to know what feature of planning conveys this increased risk. Similarly, our current assessments of suicidal intent do not neatly distinguish between suicidal and nonsuicidal self-injury. Most people who are suicidal report being ambivalent about wanting to die. However, the current standard is to consider those with zero intent as nonsuicidal, and those with all other levels of intent as suicidal. The development of methods that will more carefully quantify intent to die may improve our ability to predict and prevent suicidal behavior.

Our methods of assessing SITB presence, frequency, and characteristics also are quite crude. For example, the current state of the art in suicide assessment is retrospective self-report. Most researchers and clinicians currently do not have the ability to observe SITBs as they unfold in real time. Advances in technology, such as the development of electronic diaries and ambulatory physiological monitoring equipment, now make it possible to do so (e.g., Nock, Prinstein, & Sterba, 2009). Future efforts to use such tools to study SITBs should lead to major advances in our understanding of what these phenomena look like, and what factors trigger their occurrence.

Who Harms Themselves?

We now have comprehensive cross-national data on the epidemiology of suicidal thoughts and behaviors, as summarized above. However, complementary data are lacking for NSSI. The reason for this is that the large-scale, nationally representative surveys used to collect data on suicidal behavior have not included questions about NSSI. As the field moves forward, it will be important to include such assessments, so that we can obtain a better understanding of the actual scope of NSSI and monitor changes in the prevalence of this behavior over time. Also needed are data on how the prevalence and characteristics of NSSI may vary among those of different ages, sexes, and races/ethnicities.

Why Do People Harm Themselves?

Research over the past several decades has identified myriad risk factors for suicidal and nonsuicidal self-injury. However, much less is known about *how* or *why* these factors are associated with these outcomes. For example, we know that mental disorders increase the risk of SITBs, but we don't know why. What are the mechanisms through which this occurs? Relatedly, every theoretical model of SITBs suggests that they do not result from a single causal factor, but from the interaction of many different factors. Yet virtually all empirical studies of SITBs have examined bivariate, linear associations between putative risk factors and self-injurious outcomes. Future studies must begin to

help us understand how risk and protective factors work together to lead people to SITBs, and through what mechanisms or pathways this occurs.

How Do We Best Predict and Prevent These Behaviors?

Finally, and perhaps most importantly, we need more evidence-based methods of accurately predicting and/or preventing SITBs. Advances in our understanding of these behaviors have not yet been translated in to clinically useful tools for helping those at risk. To be sure, clinicians are assessing, monitoring, and treating people with SITBs. In fact, people in the United States are significantly more likely to receive treatment for SITBs than they were 10 years earlier (Kessler et al., 2005). But despite this increase in treatment, the rates of SITBs in the United States have remained unchanged. Building on the valuable work of many researchers, clinicians, and families, there is still a great deal of work to be done in order to decrease the enormous amount of personal suffering and broad societal costs associated with suicidal and nonsuicidal self-injury.

ACKNOWLEDGMENTS

We are grateful to Gizem Iskenderoğlu, Britta Ekdahl, Katherine White, Julia Harris, Amy Harmon, and Willow Thompson for their helpful comments on earlier versions of this chapter.

PART IV

ANXIETY, OBSESSIVE–COMPULSIVE, AND STRESS DISORDERS

CHAPTER 8

Anxiety Disorders

CHARMAINE K. HIGA-McMILLAN
SARAH E. FRANCIS
BRUCE F. CHORPITA

Fear and anxiety are common emotions that are a necessary part of the normal development of all children.[1] For some children, however, the levels of fear or anxiety are disproportionally high in relation to the cues or context (e.g., anxiety about grades for a student who is already receiving straight A's) or in relation to their developmental level (e.g., a fear of the dark for a 12-year-old). In such cases, when those emotions and their associated behaviors also lead to impairment in functioning—such as inability to attend school, make friends, perform academic tasks, or meet other developmental goals—their expression may be considered an anxiety disorder. Perhaps given the ubiquity of the emotions of fear and anxiety in everyday development, anxiety disorders collectively represent the most common type of psychiatric disorders among children (Anderson, Williams, McGee, & Silva, 1987; Costello & Angold, 1995; Kashani & Orvaschel, 1988; Kessler, Avenevoli, Costello, et al., 2012; Merikangas et al., 2010). Estimates from community samples show that one-third of adolescents will meet criteria for an anxiety disorder by the age of 18 (Merikangas et al., 2010), and studies of clinically referred samples show rates of anxiety disorders approaching 50% (Hammerness et al., 2008).

Anxiety disorders in childhood are more than just common. They are, by definition, associated with impairment in functioning, which in some cases can be extreme. For example, a considerable body of research shows that anxiety disorders in childhood are associated with later anxiety disorders, depression, substance use, and other negative mental health outcomes (Berg et al., 1989; Feehan, McGee, & Williams, 1993; Ferdinand & Verhulst, 1995; Flament et al., 1990; Keller et al., 1992; Langley, Bergman, McCracken, & Piacentini, 2004; Neal & Edelmann, 2003; Pine, Cohen, Gurley, Brook, & Ma, 1998; Woodward & Fergusson, 2001), and recent data from the National Comorbidity Study Replication—Adolescent Supplement suggests that having specific phobia, agoraphobia, social phobia (now known as social anxiety disorder), or panic disorder is the strongest predictor of most other subsequent disorders (Kessler, Avenevoli, McLaughlin, et al., 2012). Studies of community samples show that the presence of an anxiety disorder more than doubles the odds of impairment in family, educational, or peer functioning (e.g., Ezpeleta, Kessler, Erkanli, Costello, & Angold, 2001). Although this impairment can be more subtle than that caused by other disorders of childhood, such as externalizing disorders, the social costs of anxiety disorders are high. For example, a recent study estimated costs to families with clinically anxious children (e.g., health care costs, child care, missed

work or school days, lost leisure time) to be over 20 times higher than costs to families without such children (Bodden, Dirksen, & Bogels, 2008). Furthermore, when these disorders persist into adulthood, they continue to represent a high cost to society—accounting for an estimated 31.5% of 1990 adult mental health expenditures in the United States (DuPont et al., 1996). Although it is unclear whether this trend remains today, a recent systematic review found that across studies, anxiety disorders are responsible for both direct costs (e.g., treatment visits, drugs, emergency room visits), and indirect costs (e.g., reduced productivity, absence from work, early retirement), and that among the anxiety disorders, panic disorder and generalized anxiety disorder tend to shower higher direct costs than social phobia or specific phobia (Konnopka, Leichsenring, Leibing, & König, 2009).

Perhaps even more troubling than the current costs to society of this ongoing need for services is the number of children who are *not* receiving services. Data from the National Comorbidity Survey—Adolescent Supplement show that across adolescents with any of the more common disorders, the only other ones less likely to receive services than children with anxiety disorders (17.8%) are adolescents with substance use disorders (15.4%; Merikangas et al., 2011). When these numbers are compared with service utilization by adolescents with mood (37.7%), behavior (45.4%), and attentional disorders (59.8%), it is clear that adolescents with anxiety disorders significantly underutilize mental health services. To state this another way, the 2010 census reported that there are 74.18 million children under the age of 18 in the United States. Thus approximately 23.66 million children will suffer from an anxiety disorder sometime before the age of 18, and only 4.2 million of these will ever receive treatment for their illness, leaving 19.46 million children with untreated anxiety disorders to suffer in silence.

Not surprisingly, research on anxiety disorders in children has increased dramatically over the past 20 years in an effort to clarify the nature of the disorders, their impact, their etiology, and ultimately their treatment. What has emerged is a complex model detailing the interplay of genetics, temperament, early development, peers, family, and other factors in the course and expression of anxiety in children. Although far from complete, there is now a solid framework for understanding where anxiety disorders come from, how they change over time, and how they are related to each other and to other psychiatric disorders.

BRIEF HISTORICAL CONTEXT

Although a refined understanding of childhood anxiety disorders and their development is historically somewhat recent (e.g., Chorpita & Barlow, 1998; Rapee, Schniering, & Hudson, 2009; Vasey & Dadds, 2001), children's anxieties and fears have been described in the literature for over 100 years (Barrios & Hartmann, 1997). Some of the earliest research focused on case studies of childhood fears in the context of both psychoanalytic and behavioral theory. For example, in the classic case study of "Little Hans," Freud (1909/1955) defined and described several key unconscious processes operating in the development of phobia, such as the ego defense mechanisms of repression and displacement. Although the study of Little Hans has since been reconsidered (e.g., A. Freud, 1965), its value and place in psychoanalytic theory remain firmly ingrained. In a similar manner, the conditioned fear of a white laboratory rat in "Little Albert" provided early support for classical conditioning theories of the development of fears (Watson & Rayner, 1920). In this study, repeated pairings of a neutral stimulus (a white laboratory rat) and an aversive stimulus (a loud noise) resulted in the development of a conditioned fear response to the rat in 11-month-old Albert. In addition, Albert's fear generalized to a range of other stimuli, including a rabbit, a dog, a Santa Claus mask made with cotton balls, and a fur coat. Building on this work in yet another case study of a child, Mary Cover Jones (1924) described the treatment of 3-year-old Peter's fear of rabbits with a variety of behavioral techniques, including pairing the rabbit with a positive stimulus (food).

Although these and similar case studies of children served to further the interest and support for specific theoretical models and related therapeutic interventions, the study of anxiety disorders in children was essentially ignored until the latter part of the 20th century. This is both surprising and humbling, given the wealth of information and research over the last 80 years focused on the developmental progression of children's fears (e.g., see Barrios & Hartmann, 1997; Barrios & O'Dell, 1998; King, Hamilton, & Ollendick, 1988; Ollendick & King, 1991). In fact, prior to 1980, fear and anxiety reactions in children were largely ignored in psychiatric nosological systems; rather, they were studied as part of research investigating normative developmental reactions and were classified according to etiology (Hebb, 1946) or empirically based factor groupings (Miller, Barrett, Hampe, & Noble, 1972;

Ollendick, 1983; Scherer & Nakamura, 1968). That early research demonstrated that fears are common in children (e.g., Miller, 1983; Ollendick, 1983), that the number of fears reported by children declines with age (MacFarlane, Allen, & Honzik, 1954), and that the focus of the fear changes over time (e.g., Bauer, 1976). In addition, across studies, girls consistently endorse a greater number of fears than boys (Abe & Masui, 1981; Lapouse & Monk, 1958, 1959).

Formal psychiatric classification systems began to acknowledge the presence of pathological phobic reactions around the early 1950s. The first edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM; American Psychiatric Association [APA], 1952) identified phobias as psychoneurotic reactions, and in DSM-II (APA, 1968), the diagnostic category was changed to phobic neuroses. DSM-II introduced overanxious reaction as a distinct diagnostic category for children. These early DSM classification systems were heavily tied to psychoanalytic theory, purporting an unconscious process or conflict as the etiological mechanism for the phobic or overanxious reaction (Barlow, 2002). Although such theories have not stood the test of time, the inclusion of overanxious reaction in the psychiatric nosology marked a turning point for psychiatric classification, in that it began to give attention to anxiety disorders in children. Research on childhood anxiety disorders was relatively uncommon until the 1980s, and this lag may have been due in part to long-standing disagreements within the field as to what differentiates a clinical anxiety state from transient developmental fears and anxieties (Barrios & Hartmann, 1997; Strauss & Last, 1993). DSM-III (APA, 1980) and DSM-III-R (APA, 1987) represented the first attempts to delineate developmentally appropriate diagnostic criteria for phobic and other anxiety disorders in children. For example, separation anxiety disorder, avoidant disorder of childhood and adolescence, and overanxious disorder were posited as three anxiety disorders unique to childhood. At that time, children could be diagnosed with these three anxiety disorders in addition to any of the adult anxiety disorders, such as phobic disorder, obsessive–compulsive disorder, and posttraumatic stress disorder. Thus DSM-III and its revision precipitated a collection of studies examining the epidemiology and clinical characteristics of anxiety disorders in childhood (e.g., Francis, Last, & Strauss, 1987; Last, Francis, Hersen, Kazdin, & Strauss, 1987; Last, Hersen, Kazdin, Finkelstein, & Strauss, 1987; Last & Strauss, 1989). Those studies, in turn, led to changes and revisions in criteria for diagnosing anxiety disorders that were introduced in DSM-IV (APA, 1994).

This evolving classification system and the assessment instruments that followed (e.g., Silverman & Albano, 1996) enabled rigorous investigation into the prevalence, comorbidity, and severity of anxiety disorders in children. One highly consistent finding was that anxiety disorders are highly comorbid within themselves (homotypic comorbidity); that is, many children with an anxiety disorder have often had more than one—whether concurrently or across development (e.g., Benjamin, Costello, & Warren, 1990; Brady & Kendall, 1992; Kendall et al., 2010). Furthermore, a similar pattern has been shown with respect to depression and anxiety: Children with depression show elevated rates of anxiety disorders and vice versa, and anxiety disorders and depression are highly comorbid, especially across time (e.g., Costello, Mustillo, Erkanli, Keeler, & Angold, 2003, Hammerness et al., 2008).

Attempts to understand why anxiety disorders cooccur so often among themselves and with depression over the span of development led to some controversy regarding whether DSM-IV accurately represented distinct disorders, or whether it was artificially splitting subdimensions of broader pathological syndromes that truly occurred in nature (Brown, 1998; Caron & Rutter, 1991; Lilienfeld, Waldman, & Israel, 1994). Somewhat paradoxically, research has simultaneously demonstrated support for the validity of the DSM anxiety disorder syndromes (e.g., Comer & Kendall, 2004; Langer, Wood, Bergman, & Piacentini, 2010), as well as support for a single, overarching dimension underlying anxiety disorders that could perhaps better explain the high comorbidity observed among anxiety and depressive disorders (e.g., Chorpita, Albano, & Barlow, 1998; Lonigan, Carey, & Finch, 1994). Most recently, there have been attempts to unify these positions, and the emerging findings support the notion that both perspectives are likely to be valid. In other words, there is both a single underlying factor that contributes to the expression of anxiety disorders (and depression), and there are valid narrow-band syndromes of anxiety that are empirically distinct from one another. Collectively, this research paints a picture of a hierarchical model, which outlines multiple anxiety syndromes (e.g., separation anxiety, generalized anxiety, panic, social anxiety) associated with a higher-order factor common to most if not all anxiety disorders as well as depression. This hierarchical system enables us to understand the

relations among disorders (Chorpita, 2002; Clark & Watson, 1991; Craske, Rauch, et al., 2009; Joiner, Catanzaro, & Laurent, 1996; Lonigan et al., 1994). Given that such a conceptualization is relatively recent, research is only now beginning to investigate how this model behaves across the developmental span of childhood, and whether and which influences operate at the general level versus the syndrome-specific level. Before exploring these issues in more detail, this chapter first describes and examines the pathological syndromes of anxiety at the syndrome or disorder level.

DSM-5 ANXIETY DISORDERS

Although anxiety and fear are normal emotions, when they occur in the absence of typical cues and cause distress or impairment, they are referred to as anxiety disorders and phobias, respectively (Barlow, 1988). In DSM-5 (APA, 2013), children can be diagnosed with any of seven anxiety disorders: specific phobia, separation anxiety disorder, social anxiety disorder (formerly social phobia), selective mutism, panic disorder, agoraphobia, and generalized anxiety disorder. These disorders share anxious emotion as the predominant feature, expressed through specific and discrete cognitive, physiological, and behavioral reactions. Much of what distinguishes one anxiety disorder from the next is the focus of the child's anxiety. In this section, we define the core and related symptoms of specific DSM-5 anxiety disorders affecting children. A listing of DSM-5 criteria is provided in tabular form for each disorder. Whereas obsessive–compulsive disorder, posttraumatic stress disorder, and acute stress disorder were categorized with the anxiety disorders in DSM-IV, they are now categorized in DSM-5 with the obsessive–compulsive and related disorders and the trauma- and stressor-related disorders, respectively. (The reader interested in these disorders is referred to Piacentini, Chang, Snorrason, & Woods, Chapter 9, and Nader & Fletcher, Chapter 10, this volume, for a comprehensive review.)

Specific Phobia

Core Symptoms

Specific phobia (known as simple phobia prior to DSM-IV) refers to a pronounced fear of a specific situation or object (e.g., animals, heights, receiving an injection) that is disproportional to the actual danger posed and to the sociocultural context (see Table 8.1 for DSM-5 criteria). Exposure to the situation or object provokes fear, and in children, this fear may be expressed behaviorally as crying, throwing tantrums, freezing, or clinging to caregivers. The feared object or situation is actively avoided or is endured with great distress, and the fear and avoidance associated with the object causes major distress or impairment in functioning. Although DSM-IV required duration of symptoms for at least 6 months for children under the age of 18, in DSM-5 this criterion is extended to all ages, to minimize diagnosis of transient fears. Miller, Barrett, and Hampe (1974) differentiate specific phobia from normal developmental fears (e.g., a toddler's fear of strangers), in that the phobic reaction is excessive and out of proportion to the demands of the situation, cannot be reasoned away, leads to avoidance, persists over time, and interferes with activities or relationships. Although a great deal of research has examined specific phobia in children since Miller and colleagues' seminal description, the core features of the condition remain relatively unchanged.

Common fears and phobias of childhood include heights, darkness, loud noises (including thunder), injections, insects, dogs, and other small animals (Essau, Conradt, & Peterman, 2000; Silverman & Rabian, 1993; Strauss & Last, 1993). School phobia is also common in children, but the principal motivating condition for the observable avoidance behavior must be delineated for accurate differential diagnosis and prescriptive treatment planning (Kearney, 2001). A child may be diagnosed with a specific phobia of school if the fear is circumscribed to a particular school-related situation (e.g., fire drills) as opposed to fear of social or evaluative situations in the school setting, in which case social anxiety disorder might be a more appropriate diagnosis.

In the cognitive-behavioral models that have become increasingly well established over the past 40 years (Beck, Emery, & Greenberg, 2005; Kendall & MacDonald, 1993; Lang, 1968), the responses of children with phobias are often described in terms of three components of anxiety: behavioral, physiological, and cognitive. Behaviorally, avoidance is the predominant response of children with phobias. Avoidance may take the form of screaming, crying, throwing tantrums, or hiding in anticipation of confronting the feared stimulus. When contact with the phobic stimulus is unavoidable, clinging and begging caregivers for help to escape

TABLE 8.1. DSM-5 Diagnostic Criteria for Specific Phobia

A. Marked fear or anxiety about a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).

Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging.

B. The phobic object or situation almost always provokes immediate fear or anxiety.
C. The phobic object or situation is actively avoided or endured with intense fear or anxiety.
D. The fear or anxiety is out of proportion to the actual danger posed by the specific object or situation and to the sociocultural context.
E. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
F. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
G. The disturbance is not better explained by the symptoms of another mental disorder, including fear, anxiety, and avoidance of situations associated with panic-like symptoms or other incapacitating symptoms (as in agoraphobia); objects or situations related to obsessions (as in obsessive–compulsive disorder); reminders of traumatic events (as in posttraumatic stress disorder); separation from home or attachment figures (as in separation anxiety disorder); or social situations (as in social anxiety disorder).

Specify if:

Code based on the phobic stimulus:

300.29 (F40.218) Animal (e.g., spiders, insects, dogs).
300.29 (F40.228) Natural environment (e.g., heights, storms, water).
300.29 (F40.23x) Blood-injection-injury (e.g., needles, invasive medical procedures).

Coding note: Select specific ICD-10-CM code as follows: **F40.230** fear of blood; **F40.231** fear of injections and transfusions; **F40.232** fear of other medical care; or **F40.233** fear of injury.

300.29 (F40.248) Situational (e.g., airplanes, elevators, enclosed places).
300.29 (F40.298) Other (e.g., situations that may lead to choking or vomiting; in children, e.g., loud sounds or costumed characters).

Coding note: When more than one phobic stimulus is present, code all ICD-10-CM codes that apply (e.g., for fear of snakes and flying, F40.218 specific phobia, animal, and F40.248 specific phobia, situational).

Note. Reprinted with permission from *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (pp. 197–198). Copyright 2013 by the American Psychiatric Association.

the confrontation are common. Moreover, children with a specific phobia are apprehensive and hypervigilant regarding the feared stimulus. For example, children fearful of thunderstorms may scan the news or watch the sky prior to leaving home. Children with a specific phobia of dogs may go to great lengths to avoid walking down a street even when a dog is penned behind a fence. Children with specific phobia report physiological symptoms consistent with panic sensations, including rapid heart rate, sweating, hyperventilation, shakiness, and stomach upset. Cognitions of children with phobias are often characterized by catastrophic predictions or overestimation of the chance that a threatening event will occur upon exposure to the feared stimulus. Children with specific phobia also report anticipatory anxiety in the form of "What if" statements (Silverman & Rabian, 1993). For example, a child who has a phobia of thunderstorms may lament, "What if it storms on my way to school, and I get struck by lightning?"

Specifiers

According to DSM-5, there are five different kinds of specific phobia, which are identified by specifiers. The animal specifier includes fear of animals such as dogs, insects (e.g., bees, spiders, centipedes), and snakes. The natural environment specifier includes fear of events or situations occurring in the environment such as weather (e.g., storms, thunder), water, and heights. The situational specifier includes different kinds of situations such as driving, flying, crossing bridges, going through tunnels, riding elevators, or being in other enclosed spaces. The blood–injection–injury (BII) specifier includes fear of needles, invasive medical procedures,

and dental work. The last specifier, given simply as "other," is a category used when the feared object does not fall into one of the first four categories. Phobias in this category include fears of choking or vomiting, loud sounds (e.g., firecrackers, sirens), or costumed characters. In a community study of 1,035 German adolescents, of those with a diagnosis of specific phobia (3.5%), most fell into the animal or natural environment categories, and the "other" category was the least common (Essau et al., 2000). Across studies, fears of animals and heights are the most common types of specific phobia (Curtis, Magee, Eaton, Wittchen, & Kessler, 1998; Depla, ten Have, van Balkom, & de Graaf, 2008; Stinson et al., 2007).

Although there has been some speculation as to whether these categories represent clinically meaningful and valid subcategories (e.g., Antony, Brown, & Barlow, 1997), the research to date suggests that although there are some similarities, there is enough independence to warrant their continued separation. For example, using confirmatory factor analysis, Muris, Schmidt, and Merckelbach (1999) found that specific phobia symptoms in children ages 7–19 clustered into three types (animal phobia, BII, and environment/situation), and these appeared to be invariant across age and gender. In a recent review across the child, adolescent, and adult literatures in preparation for DSM-5 recommendations, both similarities and differences were found across the types (LeBeau et al., 2010). LeBeau and colleagues (2010) found similarities in age of onset, gender ratio, and treatment response, but differences in focus of fear, physiological fear response, impairment, and comorbidity. According to their review, natural environment and animal phobias share the most in common with other types, whereas the BII type shares the least with other types. As such, they recommended retaining these subcategories for the DSM-5.

Several studies have directly examined the similarities and differences across children with different types of specific phobia. In a large study of Korean children, different subtypes reportedly had different comorbidities and associated problems, suggesting distinctive profiles (Kim et al., 2010). For example, phobias of the animal subtype were associated with the presence of another anxiety disorder and oppositional defiant disorder (ODD), whereas natural environment phobias were associated with another anxiety disorder only, and BII phobias showed a significant association with attention-deficit/hyperactivity disorder (ADHD). Furthermore, although animal phobias were reported most frequently in their sample (49% of all individuals with specific phobia), children with natural environment and/or BII phobias demonstrated significantly higher scores on subscales of the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001) than children with animal phobias and children without a specific phobia diagnosis. Specifically, phobias of the natural environment type were related to higher scores on the Anxious/Depressed and Attention Problems CBCL subscales, and BII phobias were related to higher scores on the Attention Problems, Aggressive Behavior, and Externalizing Problems scales. These findings are consistent with a study by Ollendick, Öst, Reuterskiöld, and Costa (2010), who found that although there were no sociodemographic differences (age, sex, race, family structure, family income) between children with animal phobias and children with natural environment phobias, children with the natural environment type demonstrated significantly more internalizing problems, comorbid diagnoses, and lower life satisfaction than children with animal phobias; these findings suggest that the natural environment subtype is associated with greater clinical severity.

Associated Characteristics

In addition to experiencing fear and distress in the presence or anticipation of the phobic object or situation, children with a specific phobia may also demonstrate oppositional behaviors, presumably as a result of trying to avoid feared objects/situations. Adolescents with a specific phobia are likely to report somatic symptoms as well as depression (Essau et al., 2000; see section below for more details on comorbidities).

A vasovagal syncope or fainting response occurs in approximately 70–80% of adults with BII phobias (APA, 1994; Öst, Sterner, & Lindahl, 1984). Estimates specific to children are lacking at present. Decades of research and volumes on anxiety explain that this physiological response is diphasic: It is characterized by an initial brief acceleration of heart rate, followed by an immediate deceleration of heart rate and drop in blood pressure, which can lead to fainting (e.g., Barlow, 2002; Engel, 1978; Graham, Kabler, & Lunsford, 1961; Kozak & Montgomery, 1981). This response is unique to the BII type of specific phobia and is in contrast to the usual sustained acceleration of heart rate found in other specific phobia types. However, Ritz, Meuret, and Ayala (2010) recently critiqued the literature on the syncope response in the BII type. They argue that the

research to date is flawed by poor definitions of syncope; inconsistent findings on the initial acceleration of heart rate upon exposure to the feared stimulus; lack of clarity regarding which physiological parameters are important (i.e., heart rate, blood pressure, hyperventilation, adrenaline, vasopressin, etc.); lack of support for the diphasic response; and lack of emphasis on the role that cognitive variables, such as disgust and perceived loss of control, play in the fainting response. Thus, although it is clear that individuals with BII phobias show a unique pattern of physiological responses, the exact mechanisms of these physiological responses are not clearly understood.

Regardless of the mechanisms of syncope in BII phobias, it does appear that individuals with this type of specific phobia may be predisposed to this vasovagal response. For instance, according to some research, individuals with BII have an autonomic substrate that predisposes them to vasovagal syncope, and fainting during the blood phobic response is a manifestation of this underlying circulatory dysfunction (Accurso et al., 2001). It appears as though different parts of the brain are activated when individuals with BII, compared with individuals with spider phobia, are exposed to fear stimuli. When exposed to spider-related images, individuals with spider phobia showed increased activation in the dorsal anterior cingulate and anterior insula, whereas individuals with BII phobia showed increased activation in the thalamus and visual/attention areas (occipito-temporo-parietal cortex) when exposed to images related to blood, injections, and injuries (Caseras et al., 2010). However, it is unclear how or whether this functional neuroanatomical difference is related to vasovagal syncope, and whether this difference exists in children with BII.

Common Comorbidities

Several common comorbidities are found in children with specific phobia. In a community study of German adolescents, Essau and colleagues (2000) reported that 47.2% of children with specific phobia had another comorbid anxiety disorder, 36.1% had comorbid depressive disorders, 33.3% had comorbid somatoform disorders, and 8.3% had comorbid substance use disorders. Within the anxiety disorders, specific phobia co-occurred most commonly with posttraumatic stress disorder (13.9%), obsessive–compulsive disorder (11.1%), and anxiety disorder not otherwise specified (11.1%). In a community sample of adolescents, specific phobia was comorbid with separation anxiety disorder (odds ratio = 4.7) and social phobia (odds ratio = 7.2) (Lewinsohn, Zinbarg, Seeley, Lewinsohn, & Sack, 1997). In a community sample of Korean children ages 6–17, Kim and colleagues (2010) reported that 28.1% of children with specific phobia had at least one comorbid psychiatric diagnosis: 5.9% another anxiety disorder, 13% ADHD, and 13% ODD. Furthermore, in a study specifically examining the relation between depression and specific phobia by using data from the National Comorbidity Study, Choy, Fyer, and Goodwin (2007) found that individuals ages 15–54 with specific phobia experienced a significant increase in the likelihood of lifetime depression compared with those without specific phobia even after adjustments for lifetime comorbid anxiety disorders, and that the more fears an individual reported, the higher the risk for depression.

With regard to clinically referred children, Last, Perrin, Hersen, and Kazdin (1992) reported that 75% of referred children with specific phobia had a lifetime history of additional anxiety disorders, 32.5% had a lifetime history of any depressive disorder, and 22.5% had a lifetime history of any behavior disorder. The most common additional specific anxiety diagnosis was separation anxiety disorder (38.8%). In another clinic-referred sample, the most common concurrent comorbid diagnoses of specific phobia were generalized anxiety disorder, social anxiety disorder, and separation anxiety disorder (18.2%, 12.1%, and 9.1%, respectively) (Leyfer, Gallo, Cooper-Vince, & Pincus, 2013).

Epidemiology

The 12-month and lifetime prevalences for specific phobia in the National Comorbidity Study Replication—Adolescent Supplement, a large representative community sample of adolescents ages 13–18, were estimated at 15.8% and 19.3%, respectively—the highest rates of all DSM-IV psychological disorders (Kessler, Avenevoli, Costello, et al., 2012; Merikangas et al., 2010). In international community samples, 1-year prevalence of specific phobia was estimated at 7.9% in Korean children ages 6 to 17 (Kim et al., 2010), and lifetime prevalence at 3.5% in German adolescents ages 12–17 (Essau et al., 2000). In a primary care sample of children ages 8–17, the 1-year prevalence of specific phobia was 10% (Chavira, Stein, Bailey, & Stein, 2004). Among children referred to a specialty anxiety clinic, specific phobia was the third most common anxiety

disorder (27.6%) and the third most common comorbid diagnosis (10.4%) (Leyfer, Gallo, Cooper-Vince, & Pincus, 2013).

Developmental Course and Prognosis

Phobias of animals, darkness, insects, blood, and injury usually begin before age 7 (Marks & Gelder, 1966) and parallel the onset of normative fears in children, although the phobic diagnosis suggests that the fears have greater intensity and stability over time. Our understanding of the patterns of onset for childhood phobias is largely based on the retrospective report of adult phobic patients. For example, in the National Epidemiological Survey on Alcohol and Related Conditions, the mean age of onset across all types of specific phobia was 9.7 years (Stinson et al., 2007). Specifically, adult phobic patients place the onset of animal phobia between 6 and 7 years, environmental phobia at 6–12 years, blood phobia at 7–9 years, and doctors/dental/injection phobia at 9–15 years (Becker et al., 2007; Liddell & Lyons, 1978; Öst, 1987). Situational phobias tend to have a later onset, often in adolescence or young adulthood (Becker et al., 2007; Öst, 1987).

In contrast to the wealth of literature documenting the natural course of fears in children and retrospective reports from adults on the course of phobias, little empirical research has been conducted prospectively on the course of phobic disorders in childhood. In a classic and widely cited study, Agras, Chapin, and Oliveau (1972) followed a community sample of phobic individuals consisting of 10 children under the age of 20 years, and 20 adults. Participants were followed over a 5-year period, during which none received treatment for his or her phobia. Results from this study indicated that many phobic conditions resolve without active intervention. However, other researchers (e.g., Ollendick, 1979) have argued that although children improved in this study, they were not completely asymptomatic over the course of the follow-up assessment. It does appear that remission rates are higher in child and adolescent samples (Agras et al., 1972; Milne et al., 1995) than in adult samples (Stinson et al., 2007; Trumpf, Becker, Vriends, Meyer, & Margraf, 2009), and that remission rates may be associated with protective factors such as positive mental health and life satisfaction (Trumpf et al., 2009). Despite the finding that specific phobia is associated with significant psychosocial impairment (Essau et al., 2000), very few affected individuals (13.9% in adolescence and 8% in adulthood) actually seek treatment for the disorder, with mean age at first treatment in adults estimated at 31.3 years (Essau et al., 2000; Stinson et al., 2007).

Separation Anxiety Disorder

Core Symptoms

Separation anxiety disorder (hereafter abbreviated as SAD) is characterized by excessive anxiety and fear concerning separation from home or from caregivers to whom the individual is attached. DSM-5 outlines eight core symptoms, of which any three are required to meet criterion A (see Table 8.2). Three of those eight symptoms are related to distress and worry about separation from or harm to attachment figures. For example, children with SAD may worry about being kidnapped, getting lost, or having their parents involved in an accident. Three more symptoms are related to avoidance of work, school, being alone, or sleeping alone, and the last two symptoms of the first criterion involve nightmares and somatic complaints. Some research suggests that of these eight symptoms, the most common are recurrent excessive distress upon separation, reported by 87.4% of parents of children with SAD; reluctance to sleep separated from caregiver, reported by 85.7% of those parents; and reluctance to be alone, reported by 81.0% of those parents (Allen, Lavallee, Herren, Ruhe, & Schneider, 2010). Alternatively, nightmares about separation were reported by only 7.2% of parents of children with SAD (Allen et al., 2010), and have been found to be the least common symptom of SAD, dating back to DSM-III (e.g., Francis et al., 1987). Based on extensive clinical observations of children with separation anxiety, Eisen and Schaefer (2005) outlined four key symptom dimensions associated with SAD: fear of being alone, fear of abandonment, fear of physical illness, and worry about calamitous events. These dimensions correspond roughly to the DSM-5 criteria, but emphasize dimensions posited to be more relevant to treatment considerations.

As outlined in criterion A, SAD symptoms must be inappropriate for the child's age and expected developmental level, given that fears of separation are part of normative development from approximately age 7 months to 6 years (e.g., Bernstein & Borchardt, 1991). The changes from DSM-IV to DSM-5 are relatively minor, with the main emphasis involving a rewording to make the diagnosis more appropriate for adults as well as children, and removal of the criterion that the disorder onset must be prior to age 18 (the disorder has now been moved from a section on disorders diagnosed

TABLE 8.2. DSM-5 Diagnostic Criteria for Separation Anxiety Disorder

A. Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom the individual is attached, as evidenced by at least three of the following:
   1. Recurrent excessive distress when anticipating or experiencing separation from home or from major attachment figures.
   2. Persistent and excessive worry about losing major attachment figures or about possible harm to them, such as illness, injury, disasters, or death.
   3. Persistent and excessive worry about experiencing an untoward event (e.g., getting lost, being kidnapped, having an accident, becoming ill) that causes separation from a major attachment figure.
   4. Persistent reluctance or refusal to go out, away from home, to school, to work, or elsewhere because of fear of separation.
   5. Persistent and excessive fear of or reluctance about being alone or without major attachment figures at home or in other settings.
   6. Persistent reluctance or refusal to sleep away from home or to go to sleep without being near a major attachment figure.
   7. Repeated nightmares involving the theme of separation.
   8. Repeated complaints of physical symptoms (e.g., headaches, stomachaches, nausea, vomiting) when separation from major attachment figures occurs or is anticipated.

B. The fear, anxiety, or avoidance is persistent, lasting at least 4 weeks in children and adolescents and typically 6 months or more in adults.

C. The disturbance causes clinically significant distress or impairment in social, academic, occupational, or other important areas of functioning.

D. The disturbance is not better explained by another mental disorder, such as refusing to leave home because of excessive resistance to change in autism spectrum disorder; delusions or hallucinations concerning separation in psychotic disorders; refusal to go outside without a trusted companion in agoraphobia; worries about ill health or other harm befalling significant others in generalized anxiety disorder; or concerns about having an illness in illness anxiety disorder.

Note. Reprinted with permission from *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (pp. 190–191). Copyright 2013 by the American Psychiatric Association.

in childhood to the anxiety disorders section). For example, symptom 4 of criterion A now includes avoiding going to work as an example of separation-relevant avoidance (see Table 8.2). Likewise, symptom 5 has been reworded to emphasize separation from "attachment figures" as opposed to "significant adults," giving a bit more flexibility for the application of this diagnosis across the lifespan (e.g., for adults, anxiety could be triggered by separation from their offspring; Hock, McBride, & Gnezda, 1989). In addition, the duration criterion was extended from 4 weeks to 6 months for adults (minimum duration for children and adolescents is still 4 weeks), to minimize diagnosis of transient fears of separation anxiety. Finally, unchanged from DSM-IV is the requirement that the disturbance should cause marked impairment and should not be better accounted for by another diagnosis.

Associated Characteristics

Although distress about separation is one of the defining characteristics of SAD, one of the most common and interfering symptoms involves school refusal behavior. In its most extreme form, school refusal behavior involves complete avoidance of school; milder forms can include pleas to stay home, leaving school early, visits to the school nurse, or phone calls to the caregiver (Kearney, 2001). Although many anxiety disorders can co-occur with school refusal, SAD is the most common, with estimates from about 38% (Last & Strauss, 1990) to 50% (Borchardt, Giesler, Bernstein, & Crosby, 1994) among children with school refusal referred to outpatient clinics, and estimates as high as 57% among children with school refusal in inpatient settings (Borchardt et al., 1994). The association is even stronger in the other direction; for example, Last, Francis, and colleagues (1987) reported school refusal behavior in 73% of children with SAD, whereas school refusal behavior occurs only at a rate of 1% in the general population (Last & Strauss, 1990).

Another symptom that is often quite pronounced among children with separation anxiety is complaints of aches, pains, or other symptoms of physical illness. For example, Last (1991) found that somatic complaints were evidenced by 78% of children with SAD, which was the second highest rate for all anxiety disorders and

significantly higher than the rate of such complaints among all other anxiety disorders combined (53%). Furthermore, although somatic complaints commonly co-occur with other anxiety disorders and even among typical children (e.g., Alfvén, 1993), with SAD such complaints usually occur in anticipation of separation, such as at bedtime or before school. Common somatic complaints include headaches, stomachaches, or nausea (e.g., Egger, Costello, Erkanli, & Angold, 1999). Interestingly, when somatic complaints co-occur with SAD, the rates of school refusal are noted to be significantly higher (58% vs. 39%; Last, 1991).

Common Comorbidities

In a clinic-referred sample, SAD was associated with a number of concurrent comorbid anxiety diagnoses, with generalized anxiety disorder, specific phobia, and social anxiety disorder being the most common (23.7%, 21.1% and 17.1%) (Leyfer et al., 2013). In a retrospective study of SAD, 86.1% of adults who met criteria for childhood SAD also met criteria for another psychiatric disorder (Shear, Jin, Ruscio, Walters, & Kessler, 2006). Other anxiety disorders were the most common comorbid diagnoses (65.3%), with over one-third of adults with childhood SAD reporting symptoms of specific phobia and social phobia. Mood disorders (53.1%), impulse control disorders (48.3%), and substance use disorders (28.8%) were also common (Shear et al., 2006). Although panic disorder was only comorbid among 15.9% in adults with childhood SAD in Shear and colleagues' (2006) sample, considerable research has tested the idea that childhood-onset separation anxiety has a unique association with panic disorder in adulthood; both supportive results (e.g., Hayward, Wilson, Lagle, Killen, & Taylor, 2004; Silove et al., 1995) and unsupportive findings (Aschenbrand, Kendall, Webb, Safford, & Flannery-Schroeder, 2003) have been obtained. This controversial issue is discussed further in the section below on panic disorder.

Epidemiology

Twelve-month and lifetime prevalence estimates of childhood SAD range from 1 to 7.6% (Costello et al., 2003; Kessler, Avenevoli, Costello, et al., 2012; Merikangas et al., 2010; Shear et al., 2006). Among clinic-referred samples of anxious children, rates of SAD have ranged from 10 to 33%, perhaps as a function of child age and clinic type (Chavira, Garland, Yeh, McCabe, & Hough, 2009; Last, Francis, et al., 1987; Leyfer et al., 2013). Whereas many of the anxiety disorders discussed in this chapter increase in prevalence over the course of development, given the nature of the condition, SAD decreases in prevalence from childhood through adolescence (Costello et al., 2003).

Developmental Course and Prognosis

SAD is most often diagnosed in prepubertal children (Bowen, Offord, & Boyle, 1990; Kashani & Orvaschel, 1988), with an average age of onset reported at just around age 7 (Lewinsohn, Holm-Denoma, Small, Seeley, & Joiner, 2008), although separation anxiety can occur at any age (Bell-Dolan & Brazeal, 1993; Nielsen et al., 2000). In one study examining the developmental differences in the expression of separation anxiety symptoms, Francis and colleagues (1987) found age differences but not gender differences with regard to which DSM-III criteria were most frequently endorsed. Young prepubertal children (ages 5–8) were most likely to report fears of harm befalling attachment figures, nightmares, or school refusal; children ages 9–12 endorsed excessive distress at the time of separation; and adolescents (ages 13–16) most often endorsed somatic complaints and school refusal. Moreover, younger children endorsed a greater number of symptoms overall relative to adolescents.

In terms of course, research suggests that about 80% of cases of SAD remit within 18 months (Foley, Pickles, Maes, Silberg & Eaves, 2004). Similar results regarding high rates of symptom remission have been found in younger samples as well. For example, Kearney, Sims, Pursell, and Tillotson (2003) found that separation anxiety symptoms present in 3-year-olds were no longer present in about half of the children when they were assessed again 3.5 years later. Although this seems encouraging in terms of prognosis, Foley and colleagues (2004) found that 41% of separation anxiety cases still had some psychiatric disorder 18 months later, which suggests that for two out of five children with separation anxiety, the disorder may simply be replaced by something else rather than by full remission of all disorders.

Three factors were noted in children for whom an SAD diagnosis persisted over time: (1) significantly higher prevalence of ODD; (2) significantly more impairment associated with symptoms of ADHD; and (3) mothers who were less satisfied with their marriages (Foley et al., 2004). This same research has shown that children with persistent SAD are at a significantly increased risk of major depression, relative to those with

transient SAD. Other research has shown that persistent SAD is associated with poor mental health outcomes, with 73.5% of adults who had SAD as adolescents showing some psychiatric diagnosis in young adulthood, most commonly depression (e.g., Lewinsohn et al., 2008). Some cases of separation anxiety persist into adulthood, and these are associated with a high degree of impairment, neuroticism, depression, and poor response to treatment (Silove, Marnane, Wagner, Manicavasagar, & Rees, 2010).

Social Anxiety Disorder (Formerly Social Phobia)

Core Symptoms

The essential feature of social anxiety disorder (hereafter abbreviated as SOC; formerly social phobia in DSM-IV) is a marked and persistent fear of one or more social situations—including social interactions (e.g., having a conversation with another person), being observed by others (e.g., being seen while eating in a cafeteria), and performing before others (e.g., speaking in front of the class)—where the child fears that he or she will behave in a way or show anxiety symptoms that will be negatively evaluated or will offend others (see Table 8.3 for DSM-5 criteria). In children, these fears must exist in peer situations and not just in situations with adults. Exposure to the feared social or performance situation provokes fear or anxiety. In children this fear response may present as crying, having tantrums, clinging, freezing, shrinking, or refusal to speak. Children with SOC may either actively avoid these situations or endure them with marked fear or anxiety. In DSM-IV, individuals with SOC had to recognize that the fear was excessive or unreasonable, but this was not necessary for children due to cognitive-developmental reasons. However, in DSM-5 individuals of all ages do not need to recognize that the fear is excessive or unreasonable; nevertheless, the fear or anxiety must be considered out of proportion to the actual danger posed by the situation and to the sociocultural context, and if another medical condition is present (e.g., disfigurement, obesity), the fear, anxiety, or avoidance is unrelated or is excessive. Symptoms are persistent, last for 6 or more months and cause significant interference in functioning or marked distress.

TABLE 8.3. DSM-5 Diagnostic Criteria for Social Anxiety Disorder (Social Phobia)

A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).

   Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.

B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).

C. The social situations almost always provoke fear or anxiety.

   Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.

D. The social situations are avoided or endured with intense fear or anxiety.

E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.

F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.

G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.

J. If another medical condition (e.g., Parkinson's disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if:

Performance only: If the fear is restricted to speaking or performing in public.

Note. Reprinted with permission from *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (pp. 202–203). Copyright 2013 by the American Psychiatric Association.

Children and adolescents with SOC often fear a number of different situations. In a study of children with SOC, the top most feared social situations identified on the Anxiety Disorders Interview Schedule—Child and Parent Version (ADIS-C/P) included (1) speaking to new or unfamiliar people (64%%), (2) answering questions in class (49%), (3) speaking to adults (47%), (4) oral reports or reading aloud (44%), and (5) musical or athletic performances (44%) (Bernstein, Bernat, Davis & Layne, 2008). In a similar study of adolescents with SOC, the top most feared social situations identified on the ADIS-C/P included (1) oral reports or reading aloud (90.5%), (2) attending dances (90.5%), (3) parties or activity nights (87.3%), (4) asking the teacher a question or asking for help (87.3%), and (5) musical or athletic performances (87.3%) (Beidel et al., 2007). Children with SOC often have fewer friends than children without SOC, have trouble making friends, are reluctant to join group activities, and endorse feelings of loneliness on self-report measures (Beidel, Turner, & Morris, 1999; Beidel et al., 2007; Bernstein et al., 2008; La Greca, 2001).

In feared situations, a child with SOC will experience excessive concerns about embarrassment, negative evaluation, and rejection. Observations and responses of children with SOC reveal their thoughts to be characterized by negative self-focus (Alfano, Beidel, & Turner, 2006; Higa & Daleiden, 2008) and accompanied by a range of autonomic symptoms and sensations (Albano, 1995; Albano, Marten, Holt, Heimberg, & Barlow, 1995). Complaints of stomachaches and illness are common, especially among younger children. Older children and adolescents become overly concerned with the physical manifestations of anxiety, much like adults with SOC. Fears of blushing or shaking during an oral report, unsteady voice while speaking to peers, or sweating that others may notice serve to magnify a child's SOC. Research has demonstrated that the aforementioned physical responses of children with SOC are consistent with those of their adult counterparts (see Beidel & Morris, 1993, 1995). Behaviorally, younger children may manifest excessive clinging and crying, whereas older children are likely to shrink from social contact and avoid being the focus of attention.

Specifiers

DSM-IV included a generalized subtype of social phobia, which was used to indicate whether the social fear included most social situations. Data suggest that the generalized subtype is the most common form of SOC in children and adolescents (Beidel & Morris, 1993; Hofmann et al., 1999), and that individuals with generalized SOC may be distinguished from those with the nongeneralized subtype by way of earlier age of onset, greater impairment in functioning, higher risk for comorbid conditions, a greater likelihood of earlier inhibited temperament, and stronger familial transmission (Beidel & Turner, 2007; Hofmann & Barlow, 2002; Mannuzza et al., 1995). However, in a recent review of the literature, Bögels and colleagues (2010) did not find support for a unique generalized subtype. Instead, they found greater support for a dimensional view of SOC in which severity of the condition is a function of the number of feared situations, and they argued that the use of the generalized specifier is therefore not useful. For instance, in a sample of adolescents with SOC, 92% met criteria for the generalized subtype (Beidel et al., 2007). Bögels and colleagues argue that in fact, more findings support the use of a performance-only subtype than the generalized subtype; hence DSM-5 does not include a generalized subtype, but does include a performance-only specifier to indicate fears that are restricted to speaking or performing in public.

Associated Characteristics

Although some suggest that having a shy temperament may be associated with SOC, recent data from the National Comorbidity Survey Replication—Adolescent Supplement suggest that only 12% of adolescents who self-identify as shy also meet criteria for SOC (Burstein, Ameli-Grillon, & Merikangas, 2011). On the other hand, about 70% of adolescents who meet lifetime criteria for SOC self-identify as shy. Furthermore, those with SOC are more likely to meet criteria for other psychiatric disorders and to demonstrate more impairment than those who are characterized as shy. Thus shyness may be a characteristic on which individuals fall along a continuum, with adolescents meeting criteria for SOC falling at the extreme end of that continuum.

Difficulties with peers constitute a common associated problem for children and adolescents with SOC. Children with SOC receive fewer positive outcomes from their interactions with peers at school, compared with nonanxious matched controls (Spence, Donovan, & Brechman-Toussaint, 1999); are more likely to be nominated by their peers as seeking anxious solitude (Gazelle, Workman, & Allan, 2010); and are less likely to be accepted by their peers and more likely to ex-

perience peer victimization (Erath, Flanagan, & Bierman, 2007; McCabe, Antony, Summerfeldt, Liss, & Swinson, 2003). However, it is unclear whether problems with peers contribute to the development of SOC or whether symptoms of SOC precede peer problems. Some research supports the former; for instance, in the Waterloo longitudinal study, Rubin (1993) found that peer isolation in second grade was correlated with social incompetence, shyness, and unpopularity in fifth grade. More recently, in a 5-year longitudinal study, peer neglect status in the first grade was correlated with social anxiety in the fifth grade (Morris, 2004). On the other hand, in another 5-year longitudinal study, a bidirectional relation between SOC and peer rejection emerged, in which anxious withdrawal contributed to peer rejection and peer rejection contributed to anxious withdrawal (Gazelle & Ladd, 2003).

Either as a result of lack of healthy peer relationships or perhaps as a cause of negative peer relations, or both, children with SOC exhibit poor social skills (Alfano et al., 2006; Beidel et al., 1999, 2007; Ginsburg, La Greca, & Silverman, 1998; Inderbitzen-Nolan, Anderson, & Johnson, 2007; Spence et al., 1999). For example, children with SOC exhibit reduced nonverbal communication (e.g., reduced facial activity; Melfsen, Osterlow, & Florin, 2000), as well as demonstrate impaired perception of social cues (e.g., interpretation of facial expressions) relative to nonanxious controls (Melfsen & Florin, 2002; Simonian, Beidel, Turner, Berkes, & Long, 2001).

Another associated feature of SOC is the experience of self-focused attention (SFA). Cognitive models of SOC in adults propose that the experience of a socially threatening situation elicits or heightens anxious apprehension and induces a shift in focus from external stimuli to detailed monitoring of the self (Clark & Wells, 1995; Hofmann & Barlow, 2002; Rapee & Heimberg, 1997). This self-focus produces increased awareness of feared anxiety responses and interferes with processing the situation and other people's behavior. Several studies have examined SFA, which is defined as "an awareness of self-referent, internally generated information that stands in contrast to an awareness of externally generated information derived through sensory receptors" (Ingram, 1990, p. 156), and negative self-imagery (NSI), which is defined as inaccurate visual impressions of the self (Alfano, Beidel, & Turner, 2008; Clark & Wells, 1995) in younger populations. For instance, Alfano and colleagues (2008) experimentally manipulated NSI in socially anxious and nonanxious adolescents. Socially anxious adolescents reported significantly more anxiety, rated their own performance as poor, and were observed to demonstrate more anxiety and poorer performance than nonanxious adolescents with induced NSI and a control group. Furthermore, in a community sample of children and adolescents, Higa and Daleiden (2008) found that children with elevated social anxiety reported heightened SFA. In a study of physiological arousal, Anderson and Hope (2009) found that although there was no difference between adolescents with SOC and nonanxious adolescents on objective physiological arousal, adolescents with SOC perceived elevated physiological arousal during two anxiety-provoking situations. These authors suggested that socially anxious adolescents had heightened SFA, which led them to be more aware of small increases in physiological arousal compared with nonanxious adolescents, who also demonstrated slight physiological arousal but did not perceive the arousal.

Research also suggests that negative cognitions persist even after a social event has occurred. According to Clark and Wells (1995), individuals with SOC engage in ruminative processes following a social event, in which they review the distressing event and reexperience negative feelings and cognitions. In a recent study of such postevent processing, children ages 8–12 with SOC demonstrated more negative and less positive postevent processing than healthy controls (Schmitz, Kramer, Blechert, & Tuschen-Caffier, 2010). Treatment specifically designed to target such negative cognitive processing appears to effectively increase positive appraisals and decrease state anxiety in socially anxious adolescents (Parr & Cartwright-Hatton, 2009). Thus emerging research suggests that adult cognitive models of SOC may extend to younger populations.

Common Comorbidities

Across studies of clinical samples of children and adolescents with SOC, the most common comorbid diagnosis is generalized anxiety disorder; other common comorbid anxiety disorders are SAD and specific phobia (Beidel et al., 2007; Bernstein et al., 2008; Leyfer et al., 2013). Children with SOC also demonstrate significantly higher levels of depressed mood than normal children (Beidel et al., 1999, 2007; Francis, Last, & Strauss, 1992; La Greca & Lopez, 1998; Leyfer et al., 2013). In fact, SOC in childhood appears to be a risk factor for the development of depression in adolescence and adulthood. In a retrospective study of adults with

comorbid major depressive disorder and SOC, adults reported SOC onset prior to major depression onset; the mean age of onset of SOC was 11.7 years, and that of major depression was 22 years (Dalrymple & Zimmerman, 2011). Furthermore, in prospective and retrospective studies, adults with childhood and adolescent onset of SOC have greater severity and treatment-resistant forms of major depression, compared with those who have adult-onset SOC (Beesdo et al., 2007; Dalrymple & Zimmerman, 2011).

SOC in childhood and adolescence also appears to be a risk factor for the development of substance use disorders. In the Oregon longitudinal study of depression, having a diagnosis of SOC at baseline was associated with greater odds of developing alcohol and cannabis dependence, even after the researchers controlled for gender, depression, and conduct disorder (Buckner et al., 2008). In fact, the relation between SOC and alcohol and cannabis dependence remained even after other anxiety disorders were controlled for, suggesting that SOC serves as a unique risk factor for substance dependence.

Epidemiology

After specific phobia, SOC is the next most common anxiety disorder in community prevalence studies, occurring in 8.2% of adolescents and in 9.1% across the lifespan (Kessler, Avenevoli, Costello, et al., 2012; Merikangas et al., 2010). These findings are similar to findings in samples from other countries. For instance, in a study of Dutch adolescents, the 6-month prevalence rate for SOC was 6.3% (Verhulst, van der Ende, Ferdinand, & Kasius, 1997). Furthermore, rates of SOC (6%) are also similar among children receiving public mental health services (Chavira et al., 2009). Among clinic-referred samples, SOC is the second most common anxiety disorder as well, occurring in 34% of children and adolescents (Leyfer et al., 2013).

Developmental Course and Prognosis

Although the average age of onset for SOC is between 10 and 13 years (e.g., Essau et al., 2000; Strauss & Last, 1993; Wittchen, Stein, & Kessler, 1999), it is not usually diagnosed until late adolescence or early adulthood. Perhaps owing to the nature of this disorder, individuals with SOC take significantly longer to seek help after symptom onset than individuals with other anxiety disorders do (Wagner, Silove, Marnane, & Rouen, 2006), and those with the most social fears tend to be the least likely to seek treatment (Ruscio et al., 2008).

Children and adolescents with SOC are at high risk for developing major depression (Last et al., 1992), with the likelihood increasing over time. Epidemiological studies indicate that SOC in early adolescence is a direct pathway to the development of substance use disorders by middle to late adolescence (Kessler et al., 1994). It is possible that adolescents stumble into the vicious cycle of drinking to ease their social anxiety, allowing them to enter challenging situations, and then form a dependence on use of alcohol to continue their social behavior. SOC (in addition to other anxiety disorders) is also associated with significant impairment in role functioning, delayed or unstable marriage, and an overall poor quality of life (Forthofer, Kessler, Story, & Gotlib, 1996; Kessler, Foster, Saunders, & Stang, 1995; Kessler & Frank, 1997). As compared with their peers without the disorder, girls with SOC are more likely to fail to complete high school and enter college, and both young men and young women with SOC who enter college are more likely to fail to graduate (Kessler et al., 1995). Such truncated educational attainment is associated with a number of adverse life course and societal consequences (see Kessler et al., 1995), including longer dependence on the family of origin, less training for and entering into the work force, and greater demands on health care systems.

Selective Mutism

Core Symptoms

A new development for the DSM-5 is the inclusion of selective mutism (hereafter abbreviated as SM) as an anxiety disorder. In the DSM-IV, SM was classified among the disorders usually first diagnosed in infancy, childhood, or adolescence. SM is characterized by lack of speech in situations where speaking is socially expected (e.g., school, social situations) in children who have little or no trouble speaking in other situations (e.g., with family) (see Table 8.4 for DSM-5 criteria). SM symptoms must be present for at least 1 month and should not be restricted to the first month of school. Furthermore, the inability to speak is not due to a lack of knowledge of the primary language required in the social situation, and it cannot be accounted for by a communication disorder or another developmental disorder; although these can be present, they are not the main reason for the failure to speak.

TABLE 8.4. DSM-5 Diagnostic Criteria for Selective Mutism

A. Consistent failure to speak in specific social situations in which there is an expectation for speaking (e.g., at school) despite speaking in other situations.
B. The disturbance interferes with educational or occupational achievement or with social communication.
C. The duration of the disturbance is at least 1 month (not limited to the first month of school).
D. The failure to speak is not attributable to a lack of knowledge of, or comfort with, the spoken language required in the social situation.
E. The disturbance is not better explained by a communication disorder (e.g., childhood-onset fluency disorder) and does not occur exclusively during the course of autism spectrum disorder, schizophrenia, or another psychotic disorder.

Note. Reprinted with permission from *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (p. 195). Copyright 2013 by the American Psychiatric Association.

Associated Characteristics

Similar to children with SOC, children with SM demonstrate lower social competence than their peers. For instance, teachers and parents rate children with SM as lower on verbal and nonverbal social skills than children without SM (Cunningham, McHolm, & Boyle, 2006), and as lower on verbal social skills than children with other anxiety disorders (Carbone et al., 2010). Furthermore, teachers rate children with SM as lower than nonanxious controls on social assertion, self-control, and total social skills, and parents rate children with SM as lower on social responsibility and total social skills than nonanxious controls (Carbone et al., 2010).

Despite the suggestion that SM is a variant of or related to ODD, given the staunch refusal by children with SM to speak even when encouraged by adults, the research does not support this claim. Although some children with SM do exhibit some mild oppositional symptoms (Kristensen, 2001), these behaviors are similar to those exhibited by children with other anxiety disorders when confronted with feared stimuli, and their oppositional behaviors appear to be confined to settings in which they are required to speak (Cunningham, McHolm, Boyle, & Patel, 2004; Cunningham et al., 2006).

Common Comorbidities

Given the high degree of comorbidity between SM and SOC (around 65%; Black & Uhde, 1995; Kristensen, 2000), some researchers propose that SM is a developmentally specific variant of SOC in young children or a developmental precursor to SOC (Bergman, Piacentini, & McCracken, 2002). This is further supported by family history research (Black & Uhde, 1995; Chavira, Shipon-Blum, Hitchcock, Cohan, & Stein, 2007; Cohan, Price, & Stein, 2006; Kristensen & Torgersen, 2002) and by treatment outcome research, which suggests that similar treatments work for both SM and SOC (Cohan, Chavira, & Stein, 2006; Standart & Le Couteur, 2003). In addition to SOC, other common comorbid diagnoses among children with SM include communication and elimination disorders (Cohan et al., 2008; Dummit et al., 1997; Kristensen, 2000; Steinhausen & Juzi, 1996) and ODD (Yeganeh, Beidel, & Turner, 2006).

Epidemiology

SMis a rare condition, with estimates of prevalence ranging between 0.03 and 0.2% in community samples (Bergman et al., 2002; Elizur & Perednik, 2003; Kolvin & Fundudis, 1981; Kopp & Gillberg, 1997; Kumpulainen, Räsänen, Raaska, & Somppi, 1998). Given how rare SM is, few clinic-referred epidemiological studies include SM as a diagnosis in their research, and thus the prevalence among referred populations is unknown. Whereas some research suggests that there may be a higher prevalence of SM in girls than in boys (e.g., Cunningham et al., 2004; Dummit et al., 1997; Kristensen, 2000), other work suggests that it occurs equally in both sexes (e.g., Bergman et al., 2002; Elizur & Perednik, 2003).

Developmental Course and Prognosis

SM is typically first noticed upon school entry (i.e., at about the age of 5), when pressures to speak in social

situations increase (Cunningham et al., 2004; Garcia, Freeman, Francis, Miller, & Leonard, 2004; Giddan, Ross, Sechler, & Becker, 1997), although reports of onset around age 3 exist (e.g., Remschmidt, Poller, Herpertz-Dahlmann, Hennighausen, & Gutenbrunner, 2001). However, despite being first noticed at entry to school, children are typically not referred for assessment and treatment until they are older (between 6 and 9 years of age) (Ford, Sladeczek, Carlson, & Kratochwill, 1998; Kumpulainen et al., 1998; Remschmidt et al., 2001; Standart & Le Couteur, 2003). Research on the course of SM is limited; however, in a study of 24 children seeking treatment for SM, 46% showed moderate to marked improvement, whereas 54% continued to show little to no improvement in the 5–10 years after treatment (Kolvin & Fundudis, 1981). In another study of follow-up data 12 years after referral, Remschmidt and colleagues (2001) reported that 81% of individuals with SM experienced gradual amelioration of symptoms, whereas 19% experienced abrupt relief of symptoms and 19% experienced periods of relapse. Notably, among those children who show improvement in SM symptoms, the majority do so by age 10, suggesting that those who fail to show improvements by middle childhood experience a more persistent form of the disorder (Kolvin & Fundudis, 1981). Moreover, even though children may experience reductions or complete absence of SM symptoms, research suggests that they still continue to experience difficulty in social situations (Kolvin & Fundudis, 1981; Remschmidt et al., 2001).

Panic Disorder and Agoraphobia

Core Symptoms

In DSM-IV, panic disorder and agoraphobia were linked together: A diagnosis of panic disorder was made with or without agoraphobia, and agoraphobia alone had to be noted as such (agoraphobia without history of panic disorder). Notably, in DSM-5 panic disorder and agoraphobia are now unlinked, each with separate diagnostic criteria. This change was made because research suggests that a number of adolescents and adults experience agoraphobia without panic symptoms (Wittchen et al., 2008). Despite this finding, however, the available research with children and adolescents to date has primarily examined the two conditions together, and hence we discuss them together in this section.

The core defining symptom of panic disorder is the presence of panic attacks. A panic attack is a discrete period of intense fear, physical discomfort, or both that culminates within a matter of minutes and is associated with at least 4 of a list of 13 potential symptoms, including such things as pounding heart, sweating, trembling, and shortness of breath. A panic attack is not a formal DSM diagnosis and can be experienced by individuals who do not meet diagnostic criteria for panic disorder. A diagnosis of panic disorder is defined by the occurrence of recurrent unexpected panic attacks in which at least one attack was followed by a month of either of the following: persisting worry or concern about experiencing future attacks or their consequences, or a marked maladaptive change in behavior related to the attacks (see Table 8.5). In addition, the panic attacks cannot result from the direct physical effects of a substance, such as medications or caffeine, or from another medical condition (e.g., hyperthyroidism). Throughout this section, the term "panic attack" is used to refer to discrete and intense periods of fear or discomfort that might or might not occur within the context of panic disorder, whereas the term "panic disorder" is used to refer the presence of the full constellation of symptoms as outlined in Table 8.5.

Symptoms associated with panic attacks most commonly reported by children and adolescents in both clinical and community samples include palpitations, trembling or shaking, dizziness, shortness of breath, faintness, sweating, and chest pain (Diler et al., 2004; Doerfler, Connor, Volungis, & Toscano, 2007; King, Ollendick, Mattis, Yang, & Tonge, 1996; Last & Strauss, 1989; Warren & Zgourides, 1988). Although somatic symptoms are more frequently reported than cognitive symptoms, a considerable proportion of children endorse symptoms such as fears of dying or "going crazy" (Doerfler et al., 2007; King et al., 1996). Moreover, there appears to be continuity between the presentation of panic symptoms in childhood and adulthood, without evidence to suggest that different diagnostic criteria are warranted for these age groups (Biederman et al., 1997; Craske et al., 2010). Those differences that have been observed in the experience of panic symptoms among adolescents and adults have suggested that adolescents worry less than adults do about subsequent attacks and their implications, report a lower likelihood of changing their behavior in response to the attacks, and are more reticent about feelings associated with the panic attacks (Craske et al., 2010; Wittchen, Reed, & Kessler, 1998).

TABLE 8.5. DSM-5 Diagnostic Criteria for Panic Disorder

A. Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:
Note: The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate.
2. Sweating.
3. Trembling or shaking.
4. Sensations of shortness of breath or smothering.
5. Feelings of choking.
6. Chest pain or discomfort.
7. Nausea or abdominal distress.
8. Feeling dizzy, unsteady, light-headed, or faint.
9. Chills or heat sensations.
10. Paresthesias (numbness or tingling sensations).
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself).
12. Fear of losing control or "going crazy."
13. Fear of dying.

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:

1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, "going crazy").
2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations).

C. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).

D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive–compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder).

Related Symptoms

In addition to experiencing panic symptoms, children and adolescents with panic disorder may display concomitant agoraphobia, defined as the fear of being in situations from which escape may be difficult or embarrassing, or in which help is not readily available in the event of a panic attack (Kearney, Albano, Eisen, Allan, & Barlow, 1997; Masi, Favilla, Mucci, & Millepiedi, 2000). In one study (Kearney et al., 1997), situations reported as most often avoided by adolescents with panic disorder included restaurants/school cafeterias, crowds, small rooms, auditoriums, elevators, parks, grocery stores, shopping malls, being home alone, and movie theaters. Two of the most commonly endorsed symptoms of adolescents diagnosed with agoraphobia, both independently and in the presence of panic disorder, are enduring situations with intense anxiety when avoidance is not possible and needing a companion when away from home (Biederman et al., 1997; Doerfler et al., 2007). A child with panic disorder may also avoid school situations such as riding the bus or attending gym class, or may present with an outright refusal to attend school. In some cases, a parent or close friend becomes the child's "safety person," and activities are endured in the presence of this person. To ensure attendance, a parent may attempt to accompany the child during the school day. Although this behavior resembles SAD, the differential diagnosis

must be made according to the focus of the child's fear. In panic disorder, the fear is of the panic attack itself or the physical sensations accompanying the attack, and is not triggered by the fear of becoming lost or separated from a caregiver or loved one.

In a large normative sample (N = 3,021) ages 14–24 at the baseline assessment and followed longitudinally for 10 years, Wittchen and colleagues (2008) observed that agoraphobia, although often considered a related feature of panic, is a discrete disorder that can be conceptualized independently of both panic attacks and panic disorder. Specifically, in this sample, agoraphobia evidenced sex and age differences with respect to incidence and onset that were distinct from those observed with panic attacks and panic disorder. The progression and stability of agoraphobia was also different from that of panic disorder, and panic attacks were not reliably identified as a precursor to the onset of agoraphobia. These findings are consistent with the recent changes in DSM-5, suggesting that rather than an outcome of panic disorder, agoraphobia is an anxiety disorder in its own right; this builds on previous findings of agoraphobia in the absence of panic disorder in adolescents (e.g., Biederman et al., 1997; see Table 8.6 for DSM-5 criteria for agoraphobia). Although rates of agoraphobia as high as 15% have been cited in clinical samples (Biederman et al., 1997), Wittchen and colleagues (2008) reported an incidence of 0.6% for agoraphobia with no history of panic in their normative sample when employing strict DSM-IV hierarchical rules for diagnosis, and an estimated incidence of 5.3% when attending only to the endorsement of marked fear in one or more situations and disregarding whether or not there was a concurrent presence of "panic-like" symptoms. Most recently, as reported in the National Comorbidity Survey Replication—Adolescent Supple-

TABLE 8.6. DSM-5 Diagnostic Criteria for Agoraphobia

A. Marked fear or anxiety about two (or more) of the following five situations:
   1. Using public transportation (e.g., automobiles, buses, trains, ships, planes).
   2. Being in open spaces (e.g., parking lots, marketplaces, bridges).
   3. Being in enclosed places (e.g., shops, theaters, cinemas).
   4. Standing in line or being in a crowd.
   5. Being outside of the home alone.

B. The individual fears of avoids these situations because of thoughts that escape might be difficult or help might not be available in the event of developing panic-like symptoms or other incapacitating or embarrassing symptoms (e.g., fear of falling in the elderly; fear of incontinence).

C. The agoraphobic situations almost always provoke fear or anxiety.

D. The agoraphobic situations are actively avoided, require the presence of a companion, or are endured with intense fear or anxiety.

E. The fear or anxiety is out of proportion to the actual danger posed by the agoraphobic situations and to the sociocultural context.

F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.

G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. If another medical condition (e.g., inflammatory bowel disease, Parkinson's disease) is present, the fear, anxiety, or avoidance is clearly excessive.

I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder—for example, the symptoms are not confined to specific phobia, situational type; do not involve only social situations (as in social anxiety disorder); and are not related exclusively to obsessions (as in obsessive–compulsive disorder), perceived defects or flaws in physical appearance (as in body dysmorphic disorder), reminders of traumatic events (as in posttraumatic stress disorder), or fear of separation (as in separation anxiety disorder).

Note: Agoraphobia is diagnosed irrespective of the presence of panic disorder. If an individual's presentation meets criteria for panic disorder and agoraphobia, both diagnoses should be assigned.

ment, the 12-month prevalence rate for agoraphobia among a community sample of adolescents ages 13–17 years was 1.8% (Kessler, Avenevoli, Costello, et al., 2012); the lifetime prevalence of agoraphobia in this same sample was 2.4% (Merikangas et al., 2010). One possible reason for the disparity in terms of prevalence estimates and the general lack of current data pertaining to agoraphobia in the absence of panic disorder is that those with agoraphobia only have been found to be least likely to seek clinical attention for their symptoms (Wittchen et al., 2008). Evidence has also suggested that agoraphobia in the absence of panic disorder does not tend to aggregate in families, but might potentially contribute to the familial transmission of panic disorder (Nocon et al., 2008).

Associated Characteristics

Both panic attacks and panic disorder have been associated with increased risk of suicidal ideation and suicide attempts (Goodwin & Roy-Byrne, 2006). However, it has been suggested that major depression, commonly comorbid with panic disorder, might interact with panic symptoms and suicide attempts in multiple ways. For example, the co-occurrence of panic disorder and depression could result in subsequent suicide attempts; conversely, the co-occurrence of panic disorder and suicide attempts could indicate an especially severe case of depression; finally, depression might result from panic disorder, with suicide attempts indicating particularly severe cases of comorbid anxiety and depression (Goodwin & Roy-Byrne, 2006). Given the higher prevalence of suicide attempts observed in cases of comorbid panic and depression (25%) than in cases of depression (16%) or panic disorder (5.2%) alone, it seems that the association between panic and suicide attempts is best explained by the co-occurrence of depression with panic disorder (Roy-Byrne et al., 2000). More recent findings are consistent with the general hypothesis that depression may be a mediator between anxiety disorders and suicidal ideation (Greene, Chorpita, & Austin, 2009).

Respiratory illnesses also appear to be commonly associated with panic disorder. In a longitudinal study conducted with a community sample, being female, having respiratory illnesses at age 15, or having parents who had experiences with respiratory illnesses at age 18 were factors associated with increased risk of developing subsequent panic disorder with agoraphobia (Craske, Poulton, Tsao, & Plotkin, 2001). For boys, high levels of emotional reactivity, a personal history of asthma, or a greater incidence of colds and ear infections by age 3 were associated with an increased risk of later panic disorder with agoraphobia. Findings from this study suggested that experiences with respiratory illness during childhood positively differentiated individuals with and without panic disorder with agoraphobia by ages 18 and 21 from nondisordered controls (Craske et al., 2001).

Common Comorbidities

Panic disorder is frequently comorbid with other anxiety disorders (Biederman et al., 1997), as well as with depressive disorders (Bittner et al., 2004). In a longitudinal community-based study, the presence of panic disorder was associated with a greater likelihood of having at least one other DSM diagnosis (89.4% vs. 52.8%), any anxiety disorder (54.6% vs. 25.0%), any mood disorder (42.7% vs. 15.5%), and any substance disorder (60.4% vs. 27.5%) (Goodwin et al., 2004). Indeed, even the presence of panic attacks alone has been found to function as a nonspecific "risk marker" for psychopathology and comorbidity (Goodwin et al., 2004; Reed & Wittchen, 1998). Among clinical samples, significant rates of comorbid major depression (50%; Diler et al., 2004), separation anxiety (89%), and generalized anxiety (86%) have been reported (Doerfler et al., 2007). In addition to anxiety and depression, panic disorder has also been found to be comorbid with mania/hypomania, ADHD, and ODD (Doerfler et al., 2007).

The relation between SAD and panic disorder has been perhaps more closely studied than the comorbidity of panic with other diagnoses because researchers have sought to address whether separation experiences during childhood might contribute to the later development of panic (e.g., Gittelman & Klein, 1985; Mattis & Ollendick, 1997) or whether SAD might be a childhood expression of adult panic disorder. In a longitudinal study of children of parents both with and without major depression and panic disorder, Biederman and colleagues (2007) reported that SAD at baseline was the best predictor of panic disorder 5 years later. Moreover, childhood SAD has also been found to be the best predictor of childhood-onset panic disorder as reported retrospectively by adults (Biederman et al., 2005). However, although a range of studies provide support for a link between childhood SAD and the subsequent development of panic disorder, separation anxiety also

predicts other subsequent psychopathology, suggesting that it may be a nonspecific marker of later anxiety and depression rather than a specific risk factor for panic (Biederman et al., 2007; Craske et al., 2010). Children diagnosed with both disorders exhibit significantly greater levels of impairment, evidence more severe psychopathology, and have a higher rate of comorbidity than those diagnosed with SAD alone (Doerfler, Toscano, & Connor, 2008).

Epidemiology

The prevalence of panic disorder is lower among children and adolescents than other anxiety disorders (Hayward & Sanborn, 2002) with prevalence rates typically increasing during adolescence, particularly in girls (Wittchen et al., 2008). In clinical samples, prevalence rates for panic disorder have ranged from 2% (Diler et al., 2004) to 13% (Doerfler et al., 2007), whereas rates ranging from 1.6% (Reed & Wittchen, 1998) to 8.7% (Hayward et al., 2004) have been reported in community samples. Most recently, as reported in the National Comorbidity Survey Replication—Adolescent Supplement, the 12-month prevalence rate for panic disorder (with or without agoraphobia) among a community sample of adolescents ages 13–17 years was 1.9% (Kessler, Avenevoli, Costello, et al., 2012); the lifetime prevalence of panic disorder in this same sample was 2.3% (Merikangas et al., 2010). Conversely, much higher rates of panic attacks have been reported among nonreferred adolescents (e.g., Hayward et al., 2004; Wittchen et al., 2008), suggesting that as many as 16% of adolescents may have experienced a panic attack as defined by DSM (King et al., 1997).

Consistent with the pattern for adults with panic disorder, rates appear to be twice as high among adolescent girls as boys (King et al., 1997; Last & Strauss, 1989; Ollendick, Mattis, & King, 1994; Reed & Wittchen, 1998). In a longitudinal community-based study, Wittchen and colleagues (2008) noted an absence of gender differences prior to the age of 15 with respect to the rates of panic attacks observed; concerning panic disorder, although small gender differences are evident prior to age 14, differential rates of the disorder between boys and girls increased markedly between the ages of 14 and 25. Moreover, between the ages of 13 and 26 an increase in the incidence of new cases of panic disorder in girls was observed, whereas the increase of new cases among boys was less pronounced (Wittchen et al., 2008).

Developmental Course and Prognosis

At one time, panic disorder was considered an anxiety disorder of adulthood that did not occur in children and only rarely occurred in adolescents (see Kearney & Silverman, 1992; Moreau & Weissman, 1992; Nelles & Barlow, 1988). Children were thought to be incapable of forming catastrophic misinterpretations of bodily sensations—cognitions that are central to the disorder. However, over time findings have emerged supporting the existence of panic attacks and panic disorder in children and adolescents (e.g., Abelson & Alessi, 1992; Black & Robbins, 1990; Biederman et al., 1997; Doerfler et al., 2007; Hayward, Killen, Kraemer, & Taylor, 2000; Kearney, Albano, Eisen, Allan, & Barlow, 1997; Last & Strauss, 1989; Moreau & Follett, 1993; Moreau & Weissman, 1992; Ollendick, 1995; Ollendick et al., 1994). Historically, although studies have indicated the presence of panic disorder in children under the age of 13 (e.g., Biederman et al., 1997; Kearney et al., 1997), adolescents constituted the majority of these samples (e.g., Last & Strauss, 1989).

In their review of the literature specific to panic attacks and panic disorder in children, Moreau and Follett (1993) cited studies in which the onset of panic attacks occurred in children as young as between the ages of 1 and 5, but they noted that the highest rate of the onset of panic disorder appeared to be between the ages of 15 and 19. These authors also cited six case reports of panic disorder in a combined sample of 22 children, 12 of whom were under the age of 10 when symptoms of panic were first reported, as well as three studies of clinically referred children and adolescents in which 7 children and 27 adolescents were diagnosed with panic disorder (Moreau & Follett, 1993). Ollendick and colleagues (1994) similarly suggested that whereas panic attacks are common among adolescents, with 40–60% of adolescents surveyed reporting having experienced a panic attack, they are present but less frequently observed in children. Interestingly, Hayward and colleagues (1992) reported that among 754 children ages 10.3–15.6 years, the increased occurrence of panic attacks observed was associated with pubertal progression as assessed through the Tanner self-staging method, which is a means of determining an individual's level of pubertal development. Specifically, participants in this study were presented with standardized written and pictorial descriptions of five stages of physical development during puberty, and were asked to indicate which stage best depicted their pubertal

development. Overall, panic attacks were more commonly reported by girls evidencing advanced pubertal development, regardless of age (Hayward et al., 1992).

More recent studies have also documented the presence of panic disorder in children, but with similarly small numbers. Diler and colleagues (2004) observed that among 42 children diagnosed with panic disorder, 88% were age 13 or over. Biederman and colleagues (2007) similarly reported that six children in their sample experienced panic disorder with an onset prior to age 13. Two additional studies reported mean ages of onset of panic disorder during childhood (5.1 years [Biederman et al., 2005] and 11.4 years [Doerfler et al., 2008]); however, the first study was of a sample whose family members were diagnosed with panic disorder or agoraphobia, and the second was of a clinic-referred sample whose referrals were typically under the age of 10. Together these findings converge to suggest that cases of childhood panic disorder are few in number, in the context of a diagnosis that has a very low prevalence rate relative to the other anxiety disorders in this age group (Diler et al., 2004; Hayward & Sanborn, 2002; Reed & Wittchen, 1998; Wittchen et al., 1998, 2008).

The course for childhood panic disorder is typically chronic, and continuity has been found between child and adult presentations of this disorder (Biederman et al., 1997). In a community-based study employing retrospective and longitudinal prospective data collected at two time points 19.7 months apart from adolescents who were ages 14–17 at baseline, panic disorder was found to be one of the most stable anxiety disorders, even when both threshold and subthreshold diagnoses at the baseline and follow-up assessments were taken into account (Wittchen, Lieb, Pfister, & Schuster, 2000). Moreover, panic disorder was associated with one of the lowest complete remission rates (50%) (Wittchen et al., 2000), suggesting a particularly chronic and unremitting course for this disorder in the absence of intervention. In data taken from the original National Comorbidity Survey, Goodwin and Hamilton (2002) observed that individuals who had panic disorder with an early onset (at or prior to age 20) accompanied by fear (defined as feeling afraid of subsequent attacks after the first panic attack) had significantly earlier onsets of a range of comorbid disorders, had families with higher rates of psychological disorders, and had an increased risk for and lethality of suicide attempts relative to those whose panic attacks did not fit these criteria. Similarly, examination of data from the Harvard–Brown Anxiety Research Project, a prospective 15-year longitudinal study of anxiety disorders, revealed that adults with an early age of onset (less than 20 years) of panic disorder were more likely to have comorbid major depressive disorder, generalized anxiety disorder, and social phobia at baseline; and that adults with early-onset panic disorder with agoraphobia were more likely than those with late onset of these disorders to experience recurrence of symptoms after a period of remission (Ramsawh, Weisberg, Dyck, Stout & Keller, 2011). Interestingly, none of the other anxiety disorders in this study evidenced differences between early and late onset, suggesting that early-onset panic disorder represents a particularly serious condition.

Generalized Anxiety Disorder

Core Symptoms

The hallmark feature of generalized anxiety disorder (hereafter abbreviated as GAD) is extreme, uncontrollable worry about several events and activities, occurring more days than not, for at least 6 months (see Table 8.7). Unrealistic and excessive worrying about future events was present in over 95% of a clinic sample of children with overanxious disorder of childhood and adolescence (OAD) (Strauss, Lease, Last, & Francis, 1988).[2] The uncontrollable worry characteristic of GAD may be focused on a number of general life concerns, including the future, past behavior, and competence in areas such as sports, academics, and peer relationships. The most frequently reported worries of a clinical sample of children with GAD included tests/grades, natural disasters, being physically attacked, future school performance, and being bullied or scapegoated by peers (Weems, Silverman, & La Greca, 2000). It is not uncommon for children with GAD to worry about a number of adult concerns as well, such as the family finances (Bell-Dolan & Brazeal, 1993). Children with GAD may experience worry concerning performance in school, athletics, social relationships, and so on, often to the point of being perfectionistic (Bell-Dolan & Brazeal, 1993; Strauss, 1990). Consequently, these children impose exceedingly high standards for achievement on themselves and are excessively self-critical if they fail to meet these standards.

Several studies have sought to discover what distinguishes normative from clinical worry in children and adolescents. For example, research has demonstrated that although nonreferred children also worry about

TABLE 8.7. DSM-5 Diagnostic Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The individual finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):

   Note: Only one item is required in children.

   1. Restlessn or feeling keyed up or on edge.
   2. Being easily fatigued.
   3. Difficulty concentrating or mind going blank.
   4. Irritability.
   5. Muscle tension.
   6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive–compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

low-frequency events (e.g., being robbed, stabbed, shot at) (Silverman, La Greca, & Wasserstein, 1995), children with GAD may not recognize that such events have a low probability of occurrence. Other research has found that the self-reported intensity of worry, as opposed to the number of worries, differentiated clinic-referred children from nonclinical controls (Muris, Meesters, Merckelbach, Sermon, & Zwakhalen, 1998; Perrin & Last, 1997; Weems et al., 2000). Furthermore, intensity of worry is most predictive of clinician ratings of impairment for children with GAD (Layne, Bernat, Victor, & Bernstein, 2009). In fact, these studies demonstrated that nonreferred children report just as many worries as clinical samples, suggesting that the intensity of worry may be the mechanism leading to a sense of uncontrollability over the worry process (Weems et al., 2000).

Early cognitive theories conceptualized worry as an avoidant coping strategy in response to perceived future threats (Borkovec, 1994; Borkovec, Alcaine, & Behar, 2004). According to these theories, worry is a cognitive approach to identifying ways to prepare for the worst or to stop bad things from happening. Furthermore, avoidance models of worry suggest that worry as a coping strategy is negatively reinforced by the reduction of somatic responses and emotional processing of negative events, and that this reduction maintains future worry. However, a growing body of research suggests that worry actually causes physiological activation (for a thorough review, see Newman & Llera, 2011), thus calling into question the avoidance theory of worry. Newman and Llera (2011) have proposed a revised "contrast avoidance" model of worry to account for these discrepant findings. They suggest that those with GAD employ worry as a strategy to avoid a negative contrast. In other words, individuals with GAD prefer to feel chronically distressed, instead of experiencing a shift from a positive state to a negative state or from a moderately negative state to an extremely negative state (e.g., "If I expect the worst, I won't be disappointed"; Borkovec & Roemer, 1995). Newman and Llera argue that worry in their model is not reinforced by reduction in somatic responses, but rather by relief when the negative event does not occur. Research is needed to examine whether these cognitive models of worry apply to children.

In addition to emphasizing excessive and uncontrollable worry, DSM-5 outlines six specific somatic symptoms, of which one is required to make the diagnosis in children and adolescents (i.e., restlessness, fatigue, trouble concentrating, irritability, tensed muscles, and/or disturbed sleep; see Table 8.7). Similar to adults with GAD, many children with GAD are referred for treatment by their pediatricians or by gastrointestinal specialists because of significant somatic complaints (Bell-Dolan & Brazeal, 1993). In one study of children with GAD, the most common symptoms associated with worry included restlessness, difficulty concentrating, and sleep disturbance (Layne et al., 2009); another study found that children with a primary diagnosis of GAD experienced greater sleep disturbances than children with other primary anxiety disorder diagnoses (Alfano, Pina, Zerr, & Villalta, 2010). Some research has suggested that other symptoms, such as headaches, stomachaches, muscle tension, sweating, and trembling, are commonly reported among children with GAD (Eisen & Engler, 1995); however, Tracey, Chorpita, Douban, and Barlow (1997) found the muscle tension symptom to be infrequently endorsed by both children and their parents in a clinical sample evaluated with DSM-IV criteria. Similarly, Comer, Pincus, and Hofmann (2012) found in a large sample of 650 anxious children that muscle tension showed the lowest sensitivity across DSM-IV associated symptoms and had the lowest prevalence among children with GAD. On the other hand, irritability and restlessness demonstrated favorable diagnostic value in this study. Furthermore, Comer and colleagues found that in their sample, fatigue, difficulty concentrating, and sleep disturbances (which some argue overlap with symptoms of depression) continued to be related to a diagnosis of GAD even after depression was controlled for.

To explore further the distinction between somatic and worry symptoms of GAD, Higa-McMillan, Smith, Chorpita, and Hayashi (2008) examined symptoms reported on the ADIS-C/P in a clinically referred sample of 289 children and adolescents. Confirmatory factor analysis supported a two-factor model of GAD, in which worry symptoms clustered together on a separate factor from somatic symptoms. Higa-McMillan and colleagues also found that the GAD somatic factor was almost as strongly related to social phobia and major depressive disorder factors as it was to the GAD worry factor; this finding complements work by Tracey and colleagues (1997), who found that the negative predictive power of the somatic criterion for a diagnosis of GAD was low because children with other anxiety disorders also endorsed somatic symptoms. Lending further support to the idea that somatic complaints are not especially good indicators of GAD, Kendall and Pimentel (2003) found that parents consistently reported more somatic symptoms in their offspring than the children reported in themselves, and Tracey and colleagues and Kendall and Pimentel also found that adolescents reported more somatic symptoms than children. Thus it appears that somatic symptoms may not play as significant a role as worry in the phenomenology of GAD in young children as they do in adolescents and adults; this may be due to developmental differences, since younger children are still learning to become aware of somatic experiences and to link these to feelings of anxiety and worry. Nevertheless, the disparity in findings between this work and that of Comer and colleagues (2012) described above suggests the need for further research.

Associated Characteristics

Children and adolescents with GAD experience a number of associated symptoms and characteristics. For instance, in a clinical sample of 157 referred children and adolescents with GAD, feelings of tension, apprehensive expectation, negative self-image, need for reassurance, and irritability were among the most common associated symptoms, occurring in more than 75% of the sample (Masi et al., 2004). Children and teens with GAD also lack perceived control over their environment, and this relation exists even after adjustment for general negative affect (Frala, Leen-Feldner, Blumenthal, & Barreto, 2010).

A growing body of research suggests that intolerance of uncertainty (abbreviated in this discussion as IU) is a cognitive vulnerability factor of worry and GAD in adults (e.g., Dugas, Buhr, & Ladouceur, 2004), and recent work suggests that IU may play a role in GAD among children (Comer et al., 2009; Fialko, Bolton, & Perrin, 2012). IU is described as the tendency to hold a negative set of beliefs about uncertain events and their consequences or the inability to tolerate ambiguity (Koerner & Dugas, 2008). IU is considered a cognitive disposition that may confer risk for GAD because it is a higher-order vulnerability factor that predisposes individuals toward other cognitive processes involved in the maintenance of worry in adults. These processes include thought suppression and distraction strategies (i.e., cognitive avoidance [CA]); viewing events as

threats that will be difficult to cope with (i.e., negative problem orientation); and beliefs that worrying can help to solve problems and prevent feared outcomes (i.e., positive beliefs about worry [PB]) (Borkovec, 1994; Dugas, Gagnon, Ladouceur, & Freeston, 1998). Fialko and colleagues (2012) recently tested Dugas and colleagues' (1998) model of IU, examining whether worry frequency mediated the hypothesized relation between cognitive processes (IU, PB, and CA) and anxiety in a sample of 515 children and adolescents. They found that among adolescents ages 13–19, Dugas and colleagues' model fit relatively well, with IU acting as a higher-order vulnerability factor for both CA and PB. They also found support for a direct path between IU and anxiety, as well as between CA and anxiety. They concluded that IU and CA are significant risk factors not only for worries but also for anxiety. Furthermore, in children ages 7–12, they found that IU had indirect paths to anxiety via CA and worry, as well as a direct path to anxiety similar to the adolescent sample. However, they did not find support for PB in the child sample, suggesting that PB may develop over time. Taken together, it appears that IU and CA play a significant role in worries and potentially GAD in children and adolescents, just as they do in adults. In fact, functional magnetic resonance imaging research has demonstrated that IU is positively correlated with activity in frontal and limbic regions during uncertainty tasks in adolescents, further implicating this trait in the development and maintenance of GAD (Krain et al., 2008).

Common Comorbidities

Among the anxiety disorders, GAD is one of the most frequently comorbid (e.g., Masi et al., 2004). For instance, in a clinic-referred sample at a specialty clinic for anxiety and related concerns, GAD was not only the most common diagnosis (37%), but also one of the most common comorbid diagnoses (15.6%; the rate for SOC was 15.8%) (Leyfer et al., 2013). In addition, children and adolescents with GAD are often comorbid for a number of other psychiatric disorders. In the Leyfer and colleagues (2013) study of clinic-referred children, 71% of children with GAD had a comorbid diagnosis; SOC was the most common comorbid diagnosis (33.1%), followed by specific phobia (16.9%), SAD (15.4%), and depression (12.3%). However, patterns of comorbidity seem to change somewhat by sample, perhaps reflecting referral patterns. For instance, in the Masi and colleagues (2004) sample of 157 clinically referred children and adolescents with GAD, depression was the most common comorbid psychiatric diagnosis, occurring in 56% of their sample. Other comorbid conditions included specific phobia (42%), SAD (31.8%), social phobia (28%), externalizing disorder (21%), obsessive–compulsive disorder (19.7%), panic disorder (16.6%), and bipolar disorder (11%). In this sample, children with GAD were more likely than adolescents to have a comorbid diagnosis of SAD, and boys with GAD were more likely than girls to have a comorbid externalizing disorder (Masi et al., 2004).

Masi and colleagues' (2004) finding that depression is the most common comorbid diagnosis among children and adolescents with GAD is consistent with other research, which suggests that GAD may have a stronger relation to unipolar depression than it does to the other anxiety disorders. For instance, in the Higa-McMillan and colleagues (2008) study, GAD evidenced a stronger relation to depression than it did to social phobia. This finding is consistent with a substantial body of evidence in adults (e.g., Brown, Chorpita, & Barlow, 1998; Moffitt et al., 2007) as well as a study by Lahey and colleagues (2008), which also demonstrated that GAD is structurally more closely linked to the depressive disorders than to other anxiety disorders. Furthermore, epidemiological research suggests that adolescent GAD predicts depression in young adulthood (Copeland, Shanahan, Costello, & Angold, 2009).

Epidemiology

Although GAD is not uncommon in children and adolescents, with rates in community samples ranging from 0.16 to 10.8% (Cartwright-Hatton, McNicol, & Doubleday, 2006), it was the least common anxiety disorder among teens ages 13–18 reported in the National Comorbidity Study Replication—Adolescent Supplement, with 12-month prevalence rates of 1.1% and lifetime rates of 2.2% (Kessler, Avenevoli, Costello, et al., 2012; Merikangas et al., 2010). When OAD was removed from DSM-IV and replaced with GAD, community prevalence rates dropped, suggesting that some children who would have received a diagnosis of OAD in the past remain undiagnosed with GAD criteria (Beesdo, Knappe, & Pine, 2009). Nevertheless, in a recent study, GAD was the most common anxiety disorder diagnosis (37.1%) among children referred to a specialty anxiety clinic (Leyfer et al., 2013).

Developmental Course and Prognosis

Given that OAD was a diagnosis specific to childhood in DSM-III and DSM-III-R, as well as the fact that it was removed as a diagnosis from DSM-IV, research on the developmental course and prognosis for OAD and GAD in childhood are somewhat conflicting, despite some research suggesting a high degree of overlap between the two conditions (e.g., Kendall & Warman, 1996; Tracey et al., 1997). For instance, studies examining DSM-III and DSM-III-R diagnoses suggested that OAD may begin as early as age 4 years (Beitchman, Wekerle, & Hood, 1987), with the reported mean age of onset ranging from 8.8 years (Last et al., 1992) to 13.4 years (Last, Hersen, et al., 1987). On the other hand, research on GAD suggests that onset is much later—in the late teens and early 20s (Wittchen, Zhao, Kessler, & Eaton, 1994). Moreover, whereas research on OAD has found that older children present with a higher total number of overanxious symptoms and self-report significantly higher levels of anxiety and depression than younger children (Strauss et al., 1988), research on GAD suggests that there are no differences in the number or type of symptoms reported by children and adolescents with GAD (Masi et al., 2004).

Research on symptoms of GAD in community samples has also produced mixed findings on the developmental course of GAD symptoms. For instance, in one study symptoms of other anxiety disorders decreased or stabilized over the course of development, while symptoms of GAD increased among girls with age (Hale, Raaijmakers, Muris, van Hoof, & Meeus, 2008). In contrast, in another study GAD symptoms decreased between late childhood and early adolescence, followed by a slight increase in middle adolescence onward (van Oort, Greaves-Lord, Verhulst, Ormel, & Huizink, 2009). van Oort and colleagues (2009) attributed these mixed findings to the different methodologies and measures used by the two studies, and argued for additional research to sort out these differences.

SITUATIONAL AND CONTEXTUAL FACTORS

Race and Ethnicity

There is some research examining whether there are racial and ethnic differences in the presentation of anxiety symptoms among children and adolescents. In the majority of studies, the groups most commonly contrasted are European Americans, African Americans, and Hispanics/Latinos (e.g., Creveling, Varela, Weems, & Corey, 2010; Hill & Bush, 2001; Latzman et al., 2011; Walton, Johnson, & Algina, 1999; Wren et al., 2007). These examinations have yielded somewhat equivocal findings, which are particularly challenging to reconcile because of between-study variations in methodology and participants. In addition, findings across these studies generally suggest that only a small proportion of the variance observed in child anxiety is attributable to race. For example, among a normal sample of kindergarten-age children and their mothers, Hill and Bush (2001) observed similar reports of child anxiety from African American and European American mothers, but higher levels of self-reported anxiety among European American children relative to African American children. Conversely, Walton and colleagues (1999) reported that African American mothers reported lower levels of anxiety than did European American mothers, whereas African American children reported higher levels of anxiety than did European American children. However, children in Walton and colleagues' study were older (ages 10–18), and half of the sample was chronically ill. Indeed, although Walton and colleagues reported an informant × race interaction, this interaction depended on the setting of the assessment, suggesting that differences between racial groups with respect to child and maternal reports were most pronounced in anxiety-producing situations (e.g., being in a medical or dental clinic). Moreover, the informant × race interaction was present for only those children with chronic health concerns. Interestingly, in this sample child sex was also associated with child reports of anxiety, but the observed effects were dependent on both the informant (child or mother) and the setting (stressful or nonstressful).

Similarly, Latzman and colleagues (2011) observed variations for race, age, and sex in self-reported anxiety on the Revised Children's Anxiety and Depression Scale (RCADS)—a measure of anxiety and depression symptom dimensions. Specifically, in a normal school-age sample (grades 2–12), African American girls endorsed more symptoms of obsessive–compulsive disorder in elementary and middle school, whereas European American girls endorsed greater numbers of social phobia symptoms in high school. For elementary school boys, more symptoms of obsessive–compulsive disorder were observed for African American boys than for European American boys. When the data

were examined categorically and clinical cutoff scores were used, significant differences were observed only for girls: African American elementary school girls more frequently endorsed clinical levels of obsessive–compulsive disorder symptoms, and European American high school girls more frequently endorsed clinical levels of panic symptoms. However, Latzman and colleagues specifically noted that these differences, although statistically significant, were small in magnitude.

Austin and Chorpita (2004) also observed ethnic group differences for specific symptoms of anxiety in a large school-based sample of children and adolescents (N = 1,126). Comparing European American, Chinese American, Filipino American, Native Hawaiian, and Japanese American school children, all ranging in age from 7 to 18, the authors did not observe any significant between-group differences on the temperamental variable of negative affectivity underlying anxiety and depression. However, significant between-group differences were noted for separation anxiety, panic, social phobia, and obsessive–compulsive symptoms as assessed by the RCADS. Specifically, Native Hawaiians scored significantly higher than Filipino Americans, Japanese Americans, and European Americans on the separation anxiety scale, and scored significantly higher than Japanese Americans and European Americans on the panic scale. Filipino Americans scored significantly higher than Japanese Americans and European Americans on the panic scale and significantly higher than European Americans on the social phobia scale. Chinese Americans scored significantly higher than Native Hawaiians and European Americans on the social phobia scale. Finally, Native Hawaiian and Filipino Americans reported significantly higher levels of obsessive–compulsive symptoms than Japanese Americans and European Americans. Ethnicity was also found to be related to clinically elevated levels of panic and separation anxiety, such that the Native Hawaiian and Filipino American groups had proportionally more cases of clinical elevations in these domains than did Chinese Americans, Japanese Americans, and European Americans.

Conversely, in a primary care sample of children ages 8–13, Wren and colleagues (2007) noted no effects of ethnicity on the reporting of anxiety across European American, Latino, African American, Asian/Pacific, and biracial groups. However, effects of child sex and age and parental education on reports of child anxiety were observed. Similarly, in a large school-based sample (N = 1,961) of children and adolescents ages 8–18 years, Okamura and colleagues (2014) did not observe ethnic differences with respect to child-reported anxiety. However, significant ethnic group differences were observed in comparison to European American children when child anxiety was assessed via parent report. Specifically, relative to European American children, Chinese American parents reported significantly more symptoms of obsessive–compulsive disorder and rated their children as significantly higher with respect to total anxiety. Filipino American parents also reported that their children experienced significantly more symptoms of separation anxiety, panic, and total anxiety than did parents of European American children. Finally, Japanese American parents endorsed significantly more symptoms of social phobia and total anxiety for their children compared with European American parents, and Native Hawaiian parents endorsed significantly higher levels of panic symptoms for their children when compared with European American parents.

In spite of somewhat inconsistent findings with respect to the influence of race on symptoms of child anxiety, some interesting variability with respect to the relation between parenting variables and child anxiety has been reported in the context of ethnic differences. Specifically, Creveling and colleagues (2010) found perceived maternal control (e.g., the extent to which mothers made decisions for or directed the activities of their children) to be significantly related to the children's feelings of autonomy, self-confidence, and anxiety for African American, Latino, and European American children. However, among the European American children only, the relation between maternal control and child anxiety was fully mediated by a child's feeling unloved or misunderstood. Lacking confidence in one's own abilities partially mediated this relation only among European American children. For Latino children, feeling unloved or misunderstood only partially mediated the effect of maternal control on child anxiety, but neither feeling unloved nor lacking confidence mediated this relation among African American children. Finally, although ethnicity did not moderate the relations between maternal control and anxiety or between maternal control and feelings of autonomy and self-confidence, it did interact significantly with maternal control to influence feeling unloved and misunderstood; specifically, maternal control was

more strongly associated with feeling unloved and misunderstood for European American children than for African American children (Creveling et al., 2010).

Similarly, Hill and Bush (2001) observed a differential effect between African American and European American families for the extent to which parental efficacy (e.g., feelings of confidence in the parenting role) was associated with child anxiety. Specifically, in this sample of normal kindergarten-age children and their mothers, Hill and Bush observed that feelings of confidence in parenting abilities were positively associated with positive parenting practices, such as communication, and negatively associated with negative parenting practices, such as inconsistent discipline; moreover, parents who reported higher levels of efficacy had children reporting lower levels of anxiety. However, this relationship was stronger for European American families than for African American families (although the two groups did not differ in terms of mean levels of parenting efficacy), leading the authors to suggest that parental efficacy might only indirectly affect child anxiety (through positive parenting practices), or that additional extrafamilial supports might be available to African American children that compensate for lower maternal efficacy. It is important to note that no differences between African American and European American parents were noted with respect to specific parenting behaviors, including negative communication, enforcement, hostile control, inconsistent discipline, love withdrawal, and parenting efficacy. Overall, these authors suggest that parenting practices and their influence on child anxiety are generally similar across the two ethnic groups studied (Hill & Bush, 2001).

Socioeconomic Status

Recent studies examining the relation between socioeconomic status (SES) and anxiety have noted an association, although in some instances the size of this effect is small and in other instances variables often correlated with family SES (e.g., prenatal drug exposure, household density) are more strongly related to child anxiety status than is SES per se. Several studies have yielded evidence suggesting an inverse relation between familial SES and child anxiety. In a normal school sample of 216 Filipino adolescents in Hawaii, anxiety was associated with various indicators of lower status, including the education and employment of the primary family earner (Guerrero, Hishinuma, Andrade, Nishimura, & Cunanan, 2006). Similarly, Vine and colleagues (2012), in a sample of 498 school children ages 11–13, observed higher levels of physical anxiety and separation/panic anxiety (as measured by the Multidimensional Anxiety Scale for Children, or MASC) among children from lower-income families. Indeed, even after controlling for numerous other familial risk factors (including parental divorce, parental unemployment, and exposure to stressful events), Melchior and colleagues (2010) found low family income to be a significant predictor of childhood depression and anxiety among a normal sample of 941 French children ages 4–18. Specifically, children whose families had experienced low income at any time during the 8-year follow-up period were nearly twice as likely to present with internalizing symptoms as those whose families had not. Moreover, children in families whose income had either declined during the study period or remained persistently low were more likely to present with internalizing symptoms than children in families whose income had been persistently high during this time frame.

In a longitudinal study of an individual's social position (defined by current or most recent occupation for one's parent or oneself during childhood and adulthood, respectively), lower social position during childhood was associated with greater risk for adult anxiety and depression; however, this relation became nonsignificant after adjustments for adult social position and childhood psychological disorder (Stansfeld, Clark, Rodgers, Caldwell, & Power, 2011). Conversely, adult social position was associated with greater risk of anxiety and depression, even after adjustments for childhood social position and childhood disorder. Stansfeld and colleagues (2011) suggest that these findings provide only limited support for an "accumulation of risk" model, in which childhood social position confers a risk of later adult psychological disorder. However, these authors indicated that their findings provide support for a "health selection" model, whereby anxiety and depression during childhood might influence later social position in part because of difficulties in obtaining upward mobility through education and later employment opportunities. Finally, when assessing child anxiety via parent report, Okamura and colleagues (2014) noted significant inverse relations between familial SES (as defined by parental education and occupation) and total anxiety, panic, and obsessive–compulsive scores as measured by a parent version of the RCADS, such

that higher SES was associated with fewer caregiver-reported symptoms.

Other research has challenged these associations noted between family SES and child anxiety. For example, although Dirks, Boyle, and Georgiades (2011) found that psychopathology more generally accounted for a statistically significant but small proportion of variability in adult SES (2.78%), in their study neither parent- nor teacher-rated child anxiety was associated with later adult SES. Similarly, Leech, Larkby, Day, and Day (2006) followed children from the prenatal period through age 10 and observed multiple significant predictors of anxiety over time, including lower IQ scores, attention problems, prenatal exposure to marijuana, household density during prenatal development, and injuries during childhood; however, neither race nor SES was a significant long-term predictor of anxiety. Casting further doubt on the findings mentioned above, Farrell, Sijbenga, and Barrett (2009) found that instead of low SES being a risk factor for anxiety, higher anxiety was associated with higher SES. Although this effect was small, children (ages 8–12) in this study who attended high-SES schools reported higher levels of anxiety on the Spence Children's Anxiety Scale (SCAS) than did their counterparts in low-SES schools. Whether this finding is truly contradictory to those reported above is unclear, however, given that the findings of Vine and colleagues (2012) indicated a negative association between household income and child anxiety, but a positive association between neighborhood income and child anxiety. To explain these findings, Vine and colleagues suggest "group density" theories in which individuals of similar disadvantaged circumstances living together, typically in the context of low levels of income inequality, demonstrate more positive mental health outcomes. As such, the positive associations between SES and anxiety noted by both Farrell and colleagues and Vine and colleagues reflect characteristics of the larger environment in which a child resides, rather than characteristics of the specific home setting. Vine and colleagues also suggest that future studies examine potential interactions between family and neighborhood SES and their influence on anxiety.

Gender

Historically, girls have presented with higher rates of internalizing symptoms than boys, and this has been the case for anxiety in general across development. Indeed, multiple recent studies have supported higher levels of self-reported anxiety among girls than among boys in samples drawn from the United States (Okamura et al., 2014; Wren et al., 2007), Canada (Auerbach, Richardt, Kertz, & Eberhart, 2012; Jacques & Mash, 2004), Australia (Farrell et al., 2009), and Norway (Derdikman-Eiron et al., 2011; Leikanger, Ingul, & Larsson, 2012). This gender difference has also been found in studies using various self-report measures of anxiety, including the Screen for Child Anxiety Related Emotional Disorders (SCARED) (Leikanger et al., 2012; Wren et al., 2007); the MASC (Auerbach et al., 2012); the State–Trait Anxiety Inventory for Children (STAIC) (Jacques & Mash, 2004); the Revised Children's Manifest Anxiety Scale (RCMAS) (Farrell et al., 2009); the SCAS (Farrell et al., 2009); and the RCADS (Chorpita, Yim, Moffitt, Umemoto, & Francis, 2000; Okamura et al., 2014). However, although gender differences were observed in self-reported anxiety among a sample of normal children ages 8–13, Wren and colleagues (2007) and Ebesutani, Okamura, Higa-McMillan, and Chorpita (2011) both observed that such differences were not present when children were assessed via parent report. Okamura and colleagues (2014) also failed to observe significant gender differences for total anxiety scores when children were assessed via parent report, but did observe significantly higher parent reports of girls' social phobia symptoms relative to boys'. In addition, two studies noted interactions between gender and age: 15-year-old girls reported a greater increase in symptoms of social phobia than did boys (Leikanger et al., 2012); and older girls (those in grades 10 and 11) reported higher levels of anxiety than both older boys and younger girls (those in grades 4 and 5) (Jacques & Mash, 2004).

Perhaps more informative to understanding the nature of gender differences in child anxiety, however, is a recent set of findings suggesting that gender role orientation (i.e., how closely children identify with masculine or feminine roles and behaviors), rather than biological sex, accounts for more variability in anxiety symptom presentation. Muris, Meesters, and Knoops (2005) observed a positive association between femininity as identified by scores on the Children's Sex Role Inventory (Boldizar, 1991) and preference for girls' toys and activities, as well as self-reported anxiety and fear, in a sample of 209 school children ages 10–13. Although a masculine gender role orientation was negatively associated with fear, there was no significant relation observed between masculinity and

anxiety. Indeed, although girls did report more symptoms of fear and anxiety than boys did in this study, the relation between biological sex and anxiety was not observable after gender role orientation was taken into account. Moreover, the relation between gender role orientation and fear and anxiety was stronger for girls than for boys, suggesting that gender role orientation might play a larger role in understanding the expression of fear and anxiety for girls than for boys (Muris et al., 2005).

Carter, Silverman, and Jaccard (2011), in a sample of 175 clinic-referred children ages 9–13, also observed significantly higher levels of anxiety endorsed by girls than by boys, but in addition reported that both pubertal development and gender role orientation were significant predictors of anxiety symptomatology. Specifically, both boys and girls who self-reported more advanced pubertal development also self-reported higher levels of femininity and anxiety, whereas both boys and girls who endorsed higher levels of masculinity self-reported lower levels of anxiety. Similar to the findings reported by Muris and colleagues (2005), Carter and colleagues also reported that pubertal development and gender role orientation explained more variability in anxiety than did biological sex, suggesting that early pubertal development may act as a risk factor for anxiety, whereas identification with a masculine gender role orientation may serve as a protective factor. Finally, Palapattu, Kingery, and Ginsburg (2006), in a normal sample of 114 African American adolescents ages 14–19, observed a negative relation between masculinity and anxiety and a positive relation between femininity and anxiety. As reported in other studies, Palapattu and colleagues also observed higher levels of anxiety reported by girls compared with boys; however, gender role orientation explained a significant proportion of additional variance in anxiety scores beyond that accounted for by biological sex, and was considered to be more important than biological sex in explaining observed anxiety symptomatology. These authors also noted that self-esteem acted as a protective factor with respect to anxiety in this sample, and that this relation was most marked among those endorsing high levels of femininity (Palapattu et al., 2006). Together, these findings suggest rather reliable differences between girls and boys with respect to their experience of symptoms of anxiety, but also indicate that the traits encompassing feminine and masculine gender role orientations might better explain individual differences in anxious symptomatology.

Age

Findings with respect to age differences in anxiety generally suggest stability over time, although the nature of the anxiety does change across development (Weems & Costa, 2005). Specifically, younger children generally report more fears than do older children (Broeren & Muris, 2009), whereas generalized anxiety (Broeren & Muris, 2009) and social anxieties (Ranta et al., 2007; Weems & Costa, 2005) tend to peak during adolescence, particularly among girls (Leikanger et al., 2012). Specifically, Weems and Costa (2005), in a cross-sectional study of 145 normal children in three age groups (6–9, 10–13, and 14–17), noted that concerns regarding separation were most common in the youngest age group; fears related to death and danger were most prevalent in the middle age group; and social and performance concerns were those most often reported by the oldest cohort of adolescents. Similarly, Broeren and Muris (2009), in a normal sample of 226 Dutch children, noted higher fear scores among younger children (ages 4–5) and higher generalized anxiety scores among older children (ages 6–9). With respect to fear, in a sample of 388 school children ages 4–13, an inverse relation between anxiety sensitivity (i.e., the belief that symptoms of anxiety can be harmful; Reiss, Peterson, Gursky, & McNally, 1986) and age was also observed, such that older children reported less fear associated with physical symptoms of anxiety (Muris, Mayer, Freher, Duncan, & van den Hout, 2010). The extent to which specific symptoms are associated with anxiety also changes with age (Boylan, Miller, Vaillancourt, & Szatmari, 2011). Specifically, in a sample of 1,329 children ages 4–7 who were studied prospectively for a period of 8 years, the factor structure of anxiety and depression remained stable across development, whereas the specific items related to each factor changed with age. These findings suggest that the presence of anxious symptomatology is relatively stable over time, and that only the specific expression of fears and worries tends to change with development (Weems & Costa, 2005). Along those lines, Broeren and Muris concluded that (with the exception of specific fears, which clearly exhibit an age-related effect) the overall contribution of developmental factors to the expression of anxiety symptoms is small, and that other factors play a more important role in explaining the development and maintenance of anxiety disorders.

More generally, diagnoses of anxiety have also been observed to be stable over time (Carballo et al., 2010)

with specific symptoms aggregating into disorder-specific clusters among children as young as ages 2–3 (Mian, Godoy, Briggs-Gowan, & Carter, 2012). Carballo and colleagues (2010) followed a sample of 1,869 children between the ages of 2 and 18 at first diagnosis prospectively for a period of 14 years. They noted high diagnostic stability across time for all of the *International Classification of Diseases*, 10th revision (ICD-10) anxiety disorders studied, including phobic disorders, social anxiety disorders, obsessive–compulsive disorder, stress-related disorders, and "other" anxiety disorders. Moreover, Turner and Barrett (2003) demonstrated that the differentiation between anxiety and depression was stable across age. Similarly, Mian and colleagues (2012), in a sample of 1,110 children ages 22.6–47.9 months, found that symptoms of anxiety in this age group consistently aggregated into symptom clusters matching current diagnostic categories of generalized anxiety, obsessive–compulsive symptoms, separation anxiety, and social phobia. Such findings suggest that even at this early stage of development, specific clinical presentations of anxiety can be observed. Finally, in a review of behavioral genetic studies of anxiety, Franić, Middeldorp, Dolan, Ligthart, and Boomsma (2010) noted that the heritability of anxiety increases over time, as the influence of shared environmental factors lessens throughout the maturation from childhood to adolescence. Moreover, these authors suggest that the temporal stability of anxiety may be stronger than has previously been reported in longitudinal studies of anxiety, given the use of different reporters across development: Parents are often queried to assess the symptomatology of younger children, whereas older children typically provide self-reports of their experience of anxiety (Franić et al., 2010). Taken together, findings with respect to age differences in the presentation of anxiety suggest relative stability over time in the context of changing specific presentations across age.

ETIOLOGY

Genetics

Symptoms of anxiety aggregate in families (e.g., Turner, Beidel, & Costello, 1987); that is, anxious children are more likely to have anxious parents (e.g., Rosenbaum et al., 1992), and anxious parents are more likely to have anxious children (e.g., Beidel & Turner, 1997). Given that parents and children typically share both genetic material and a familial environment, the challenge has been to determine the respective contributions of each of these factors to the development of anxiety. Twin studies are one of the most common means of obtaining estimates of the heritability of specific phenotypic presentations and allow for the variance in a given phenotype to be attributed to three sources: (1) additive genetic influences, (2) common or shared environmental factors, and (3) nonshared environmental experiences (Gregory & Eley, 2007). As defined by Gregory and Eley (2007) in their comprehensive review of the genetic literature specific to child anxiety, additive genetic effects represent the sum of the effects of specific alleles, whereas shared environmental factors consist of experiences that effectively increase similarity among family members. In contrast, nonshared environmental factors represent those experiences that result in family members differing from one another (in most models, these factors also include measurement error).

Interestingly, the relative contributions of genetic and shared environmental factors appear to be inversely related to one another over the course of development (Bartels et al., 2007). Measuring anxiety with broad-syndrome self-report, teacher report, and parent report scales, Bartels and colleagues (2007) observed in a sample of twins followed from birth to age 12 years that genetic influences tended to decrease over development, while shared environmental influences increased (see also Eley et al., 2003; Hallett, Ronald, Rijsdijk, & Eley, 2009). Although the relative contributions of these influences vary across development, genetic factors explained the largest proportion of variability in anxiety among young children (Bartels et al., 2007). In contrast, nonshared environmental contributions remained more constant across development, but tended to account for the least amount of variance in anxiety presentations (Bartels et al., 2007). These effects were reported for both boys and girls, with somewhat stronger genetic effects observed for boys than girls, but findings have not yet suggested that different genes are responsible for different expressions of anxiety between the sexes (Bartels et al., 2007; Franić et al., 2010; Kendler, Gardner, & Lichtenstein, 2008).

Genetic and Environmental Contributions to Anxiety

In two studies assessing the relative contributions of genetic and environmental factors to anxiety-related dimensions (e.g., negative cognitions, negative affect, fear, social anxiety, obsessive–compulsive behaviors)

(Eley et al., 2003; Hallett et al., 2009), genetic factors were found to account for the largest proportion of variability, consistent with findings reported by Bartels and colleagues (2007). Specifically, across three different developmental time points from ages 4 to 9, genetic influences accounted for 39–64% of the variance in phenotypic presentation (Eley et al., 2003; Hallett et al., 2009). In contrast, shared environmental factors accounted for the lowest proportion of variability (3–21% across these three age groups), but, consistent again with observations made by Bartels and colleagues, the influence of shared environmental factors was lowest among the 4-year-old sample (range = 3–17%) and highest among the 9-year-old sample (range = 11–23%); the converse was true of the genetic influences, which were highest among 4-year-olds (range = 39–64%) and lowest among 9-year-olds (range = 46–58%). Nonshared environmental effects consistently accounted for approximately one-third of the variance in presentation (range = 22–43%) (Eley et al., 2003; Hallett et al., 2009).

More specifically, for 4-year-olds, obsessive–compulsive behaviors and shyness/inhibition were the behaviors most influenced by genetic factors (with 54% and 64% of the variance attributed to genetic influences, respectively), whereas shared environmental influences were strongest for separation anxiety (with 35% of the variance being attributed to such influences) (Eley et al., 2003). Among older children, negative affect (i.e., general emotional distress common to both anxiety and depression, comprising feelings of fear, anger, and sadness; Joiner et al., 1996; Watson & Clark, 1984) was the factor least influenced by genetic factors (with heritability estimates of .50 at age 7 and .46 at age 9), whereas social anxiety at age 7 (.61) and fear at age 9 (.58) yielded the highest heritability estimates (Hallett et al., 2009).

In research examining the symptom syndromes of specific phobia, separation anxiety, and social phobia among a twin sample ages 6–6½ years, the heritability estimate was significant for specific phobia (46%), but not for separation anxiety (21%) or social phobia (14%) (Eley, Rijsdijk, Perrin, O'Connor, & Bolton, 2008). Although genetic, shared environmental, and nonshared environmental influences each significantly contributed to specific phobia, only nonshared environmental influences were significantly associated with separation anxiety (59%) and social phobia (76%) (Eley, Rijsdijk, et al., 2008). Similarly, in another study, separation anxiety symptoms were attributable largely to nonshared environmental factors (50%, in contrast to 22% genetic and 28% shared environmental factors), and specific phobia symptoms were most attributable to genetic factors (58%, in contrast to 19% shared and 23% nonshared environmental influences) (Bolton et al., 2006). Interestingly, however, when these symptom presentations met diagnostic criteria, the largest proportion of variability in both SAD and specific phobia was due to genetic factors (73% and 60%, respectively). For both disorder categories, shared environmental influences failed to contribute to the variance, whereas approximately one-third of variance was attributable to nonshared environmental influences (Bolton et al., 2006).

In contrast to the findings reported above, Ogliari and colleagues (2006, 2010) observed that the best-fitting multivariate models for their twin data were those in which contributions were made only by genetic and nonshared environmental factors to each of four diagnostic presentations of anxiety assessed by the SCARED (Birmaher et al., 1997). Specifically, for generalized anxiety, social phobia, panic, and separation anxiety, approximately half (49–60%) of the variability observed in these presentations was attributable to genetic factors, whereas 40–51% of variability was attributable to nonshared environmental factors. However, as noted by the authors, these discrepant findings might be due in part to methodological differences between the two sets of studies—namely, the use of child self-report questionnaires assessing DSM-IV symptom criteria with a considerably smaller sample (i.e., 378 twin pairs; Ogliari et al., 2006, 2010), in contrast to maternal reports of anxiety-related behaviors in relatively larger samples (i.e., samples ranging from 854 to 4,564 twin pairs; Eley et al., 2003; Eley, Rijsdijk, et al., 2008; Hallett et al., 2009). Yet, using parent and child reports obtained via the Achenbach CBCL and Youth Self-Report form, respectively, Kendler and colleagues (2008) also failed to find evidence of shared environmental influences on symptoms of anxiety and depression, instead reporting significant genetic contributions with heritability estimates ranging from 72 to 89%. Clearly, continued research is required to elucidate the role of shared environmental factors in the phenotypic expression of anxiety.

Genetic and Environmental Influences on Comorbidity

In addition to looking at the relative contributions of genetic, shared environmental, and nonshared environmental influences to specific anxiety-related dimen-

sions (i.e., general distress or negative mood, separation anxiety, fears, obsessive–compulsive behaviors, and shyness/inhibition), Eley and colleagues (2003) examined how these three factors influenced shared variance among these anxiety-related dimensions and thus might contribute to the comorbidity of anxiety disorders. Shared genetic contributions accounted for 12–62% of the covariance between factors, with general distress and shyness/inhibition sharing considerable overlap with the other scales. In contrast, obsessive–compulsive behaviors shared little genetic overlap with the other scales. Shared environmental factors accounted for 43% of the overlap between separation anxiety and fears and between fears and obsessive–compulsive behaviors, while accounting for 78% of the covariation between separation anxiety and obsessive–compulsive behaviors. Across scales, nonshared environmental influences tended to account for relatively low levels (10–36%) of overlap between the behaviors (Eley et al., 2003). Hallett and colleagues (2009) observed that the highest proportion of variability in symptom overlap was accounted for by shared environmental factors (22–57%) and genetic factors (24–57%), with less of the overlap between phenotypes being attributable to nonshared environmental influences (11–36%). Moreover, the results of Hallett and colleagues' study on the one hand suggest genetic specificity, such that rather than identifying a single underlying factor related to multiple lower-order factors, the data supported independent factors that did not share high levels of genetic overlap. On the other hand, relatively high correlations were observed between the negative cognitions subscale and subscales for each of the other anxiety-related behaviors, suggesting that 42–57% of the overlap of each scale with negative cognitions was attributable to genetic factors. Together, such findings are in contrast to the "generalist genes" theory, which suggests that genes confer only a general risk for anxiety, whereas environmental influences are responsible for specific presentations. Specifically, the findings of Hallett and colleagues suggest that genetic influences are active at both a general level (e.g., negative cognitions) and a specific level (e.g., social anxiety). Collectively, the findings reported by Eley and colleagues and Hallett and colleagues indicate that both genetic and shared environmental factors contribute to comorbidity between anxiety symptom presentations, with nonshared environmental influences playing a smaller role.

With respect to the "symptom syndrome" phenotypes of specific phobia, separation anxiety, and social phobia (defined by meeting the DSM-IV symptom criteria for a specific disorder except for the diagnostic criterion regarding level of impairment), shared environmental influences contributed significantly to the comorbidity of each of these syndromes with the other. Specifically, correlations among the syndrome pairs ranged from .98 to .99. The comorbidity between specific phobia and social phobia represented the only case in which nonshared environmental effects exerted a significant influence (r = .33) (Eley, Rijsdijk, et al., 2008). The relations between separation anxiety and either specific phobia or social phobia were not significantly accounted for by genetic factors (Eley, Rijsdijk, et al., 2008). Findings that shared environmental influences contribute to the comorbidity among these three syndromes suggest that specific aspects of the family environment (e.g., those that are shared and serve to make family members more similar to one another) may have a general influence on multiple anxiety presentations; conversely, the more modest contributions of genetic factors to the overlap of these syndromes suggest that different biological processes may underlie these varying phenotypic presentations (Eley, Rijsdijk, et al., 2008).

Similar to those findings reported above with respect to genetic and environmental influences on anxiety, Ogliari and colleagues (2006, 2010) found no evidence that shared environmental influences contribute to observed comorbidity in anxiety presentations. These authors report considerable genetic influences on comorbidity (ranging from 40% for the overlap of generalized anxiety and social phobia to 61% for the overlap between social phobia and panic), with only modest influences of nonshared environmental factors (ranging from 1% for social phobia and panic to 34% for generalized anxiety and panic) (Ogliari et al., 2006, 2010). Again, as indicated above, such differences across studies could be attributable to methodological variations across the studies. Accordingly, further study is required to ascertain not only the relative contributions of genetic and environmental influences to anxiety symptomatology and comorbidity, but also the specific role that shared environmental factors play in these phenotypes and their overlap.

Genetic Influences across Development

In the context of efforts to ascertain the relative contributions of genetic and environmental factors to anxiety, the changing role of genetic influences over the

course of development cannot be ignored. Kendler and colleagues (2008) report support for a dynamic model of genetic influences on anxiety, in which new genetic effects continue to emerge across development (innovation) while the overall impact of genetic factors declines with increasing age (attenuation).

Other studies have examined the nature of genetic influences across development in the context of heterotypic (i.e., an earlier disorder predicts a different subsequent disorder) and homotypic (i.e., an earlier disorder predicts the same disorder later in time) continuity. For example, findings from a recent study suggest heterotypic continuity between SAD during childhood and adult-onset panic attacks, such that these two phenotypes are linked in a way that has not been observed for OAD during childhood and later panic attacks (Roberson-Nay, Eaves, Hettema, Kendler, & Silberg, 2012). Furthermore, in an investigation of homotypic and heterotypic continuity and the extent to which genetic and environmental factors influence these relations during development, stability in anxiety-related symptoms over time (homotypic continuity) was largely attributable to genetic factors, whereas shared environmental factors exerted the greatest influence over heterotypic continuity (Trzaskowski, Zavos, Haworth, Plomin, & Eley, 2012). Specifically, in their sample of twin pairs (the same sample investigated by Hallett et al., 2009) assessed at ages 7 and 9, Trzaskowski and colleagues (2012) found within-trait correlations over time ranging from .45 for negative affect to .54 for social anxiety, with 57–67% of this continuity attributable to genetic factors. Conversely, only 8% (negative cognitions) to 28% (negative affect) of this continuity was attributable to shared environmental influences, and only 13% (fear) to 26% (negative cognitions) was attributable to nonshared environmental factors. In contrast, heterotypic continuity was most influenced by shared environmental factors, which accounted for 21% (negative cognitions at age 7, negative affect at age 9) to 62% (negative affect at age 7, fear at age 9) of the covariance between these traits over time. Genetic influences on heterotypic continuity were generally lower (28–66%; genetic factors did explain 66% of the covariance between negative cognitions at age 7 and negative affect at age 9), as were nonshared environmental influences (4–28%). With respect to the strong contribution of genetic factors to the relation between early negative cognitions and later negative affect, Trzaskowski and colleagues indicate that the scales assessing these traits contain several symptoms that are shared between anxiety and depression; accordingly, the heterotypic continuity observed between these traits may be indicative of the more general relation between anxiety and depression over time. Moreover, the substantial influence of shared environmental factors on the relation between early negative affect and later fear suggests that parents may play a significant role in the development of fear during childhood. Most importantly, perhaps, these findings illustrate that the relative contributions of genetic and environmental factors to the homotypic and heterotypic continuity of anxiety vary as a function of the specific traits assessed (Trzaskowski et al., 2012).

In an effort to identify individuals at risk for specific disorders, researchers have begun studying "endophenotypes," which are "intermediate phenotypes that are more proximal to the genes influencing a disorder than its signs and symptoms, and can be considered risk markers of a disorder" (Gregory & Eley, 2007, p. 208). One endophenotype specific to anxiety might be anxiety sensitivity, reported by Eley, Gregory, Clark, and Ehlers (2007) to be heritable among a sample of 8-year-old twins and to share considerable genetic overlap with symptoms of panic. As such, it might serve as a useful indicator of risk for the development of panic. Anxiety sensitivity has also been found to demonstrate a stability over time that is largely due to genetic factors (61%), whereas nonshared environmental influences (39%) are associated with specific variations at individual assessment points (Zavos, Gregory, & Eley, 2012). More specifically, in their investigation of 1,300 twin and sibling pairs across three time points (midadolescence, late adolescence, and early adulthood), Zavos and colleagues (2012) observed moderate estimates of heritability for anxiety sensitivity across development, suggesting genetic continuity, but also noted new genetic influences emerging in late adolescence, consistent with Kendler and colleagues' (2008) findings of genetic innovation. Across all time points, shared environmental contributions were nonsignificant (Zavos et al., 2012). These findings suggest support for both learning and trait hypotheses, such that the considerable contribution of nonshared environmental factors at each time point (41–54%) underscores the importance of learning in the development and expression of such symptoms, whereas the genetic stability of these symptoms indicates a trait-like variable (Zavos et al., 2012). However, these findings must be interpreted with caution, given the equivocal support that has been observed for the validity of the construct of anxiety sensitivity in children; specifically, no empirical support currently exists

to discriminate this sensitivity from fear or trait anxiety in children (e.g., Chorpita & Daleiden, 2000; Chorpita & Lilienfeld, 1999). Accordingly, rather than providing data with respect to an endophenotype of anxiety, these findings might instead refer to the general construct—or phenotype—of trait anxiety.

The Role of Specific Genes in Anxiety

As Gregory and Eley (2007) note in their review of the literature, research attempting to identify specific genes responsible for specific anxiety presentations has been limited by the fact that numerous genes are typically responsible for any given phenotypic expression. Gregory and Eley state that so-called "linkage studies," in which specific genes responsible for specific phenotypic expressions are sought, are of limited utility; in contrast, however, "association studies," based on comparing the frequencies of alleles in identified case and control participants, can be more informative with respect to specific genetic influences on anxiety presentations. Accordingly, a small group of recent studies have suggested that the serotonin transporter (5-HTT) allele might be implicated in the development of anxiety. As noted in their review of these studies among children and adolescents, Murray, Creswell, and Cooper (2009) indicate that the findings yielded to date in this area of inquiry are contradictory and inconsistent. Specifically, some studies have failed to find a significant relation between the 5-HTT gene and features of anxiety (Schmidt, Fox, Rubin, Hu, & Hamer, 2002). In other instances, relations between the 5-HTT allele and anxiety-related behaviors have been observed, but with different forms of the allele (e.g., Arbelle et al., 2003; Battaglia et al., 2005), suggesting that additional factors might moderate an existent relation between this gene and anxiety symptom presentations (Murray et al., 2009).

Indeed, a gene × environment interaction emerged between the 5-HTT gene and maternal reports of low social support, such that the short 5-HTT allele was associated with higher levels of behavioral inhibition during childhood, but only in the context of low social support (Fox et al., 2005). Similarly, a gene × environment interaction was observed by which the 5-HTT gene interacted with prenatal maternal anxiety symptoms to influence the risk for later emotional difficulties (Tiemeier et al., 2012). Finally, evidence of another significant gene × environment interaction was supported: Stressful life events presented a greater risk for anxiety and depression in the context of a specific 5-HTT genotype (i.e., one that is associated with lower serotonin transcriptional efficiency) (Petersen et al., 2012).

In addition, one genetic disorder—22q11.2 deletion syndrome, or 22qDS—may be linked to the anxiety disorders. Specifically, in a review study of children and adolescents (ages 4–19) diagnosed with 22qDS, across seven independent studies 39% of participants met diagnostic criteria for one or more anxiety disorder, whereas only 17% of controls did; indeed, of the psychiatric disorders reported in these studies, anxiety disorders were the most common (Jolin, Weller, & Weller, 2012). Six of these studies included data with respect to specific DSM-IV anxiety disorders, indicating that most common among children with 22qDS was specific phobia (31%), followed by GAD (13%), SAD (9%), and obsessive–compulsive disorder (8%). Collectively, such findings are far from conclusive with respect to identifying specific genes that are active in the expression of anxiety, but they do suggest potential avenues for future study.

Neurobiology

Although it is known from animal research and psychopharmacological treatment research that several neurotransmitters (e.g., gamma-aminobutyric acid, norepinephrine, serotonin, substance P) are implicated in the anxiety disorders, most research on the neuropsychopathology of child anxiety has focused on the neuroanatomy of the brain. This research on neuroanatomy of psychological disorders, known as "affective neuroscience" (Vasa & Pine, 2004), examines structural differences in the brains of individuals with and without anxiety (or inhibited temperament) with magnetic resonance imaging (MRI) and the way the brain functions in individuals with and without anxiety disorders with functional MRI (fMRI) and positron emission tomography (PET) scans. Structural MRI techniques focus primarily on the size of different brain matter, whereas the functional imaging techniques allow researchers to examine how the brain responds to certain stimuli or events. As is typical for this type of research, animal models are frequently used to develop hypotheses about neural circuits in humans (LeDoux, 1995, 1998).

Brain Structure and Function

In a recent large study (N = 265) of personality traits and brain structure in healthy adults, among the Big

Five personality traits (i.e., Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness), Neuroticism was identified as the trait most clearly linked to brain structure (Bjornebekk et al., 2013). Neuroticism has been shown to be a risk factor for the development of psychopathology, especially anxiety and depression (e.g., Bienvenu, Hettema, Neale, Prescott, & Kendler, 2007; Cox, MacPherson, Enns, & McWilliams, 2004; Hettema, Neale, Myers, Prescott, & Kendler, 2006). In the Bjornebekk and colleagues (2013) study, higher anxiety, depression, and vulnerability to stress were associated with smaller total brain volume, decrease in white matter microstructure, and smaller cortical surface area in the frontotemporal regions.

AMYGDALA

With regard to specific brain regions among individuals with anxiety disorders, research has primarily implicated the amygdala, a part of the limbic system located in the temporal lobe responsible for processing emotional reactions and memories. The location of the amygdala allows it to integrate information from sensory inputs from the cortex, thalamus, and hippocampus, and to send out information through the hypothalamus, brainstem, and cortex. In addition to focusing on the amygdala, contemporary models of anxiety disorders highlight a network of brain regions, including the insular cortex, prefrontal cortex (PFC), hippocampus, orbitofrontal cortex (OFC), and anterior cingulate cortex (ACC) (Craske, Rauch, et al., 2009). Using MRI, Schienle, Ebner, and Schafer (2011) found that adults with GAD had larger volumes of the amygdala and the dorsomedial PFC than healthy adults had, and self-reports on symptom severity were positively correlated with volumes of the dorsomedial PFC and the ACC. Similarly, in an MRI study of children and adolescents with GAD, right and total amygdala volumes were larger than those of healthy controls, whereas intracranial, cerebral, cerebral gray and white matter, temporal lobe, hippocampal, and basal ganglia volumes and measures of the midsagittal area of the corpus callosum did not differ between groups (De Bellis et al., 2000). Another structural MRI study has implicated the superior temporal gyrus (STG), a ridge on the temporal cortex, in GAD in children. In this study, children and adolescents with GAD had larger total matter, white matter, and gray matter of the STG than healthy controls had (De Bellis et al., 2002). Furthermore, these investigators reported more pronounced asymmetry (i.e., right side larger than left) in total and STG white matter volumes in children and adolescents with GAD than in healthy controls, and there was a significant correlation between STG white matter asymmetry and child self-reported anxiety.

Not all findings are consistent, however. For example, in one study gray matter volume in the amygdala was significantly reduced in children and adolescents with anxiety disorders compared with healthy controls (Milham et al., 2005). It is unclear why these findings contradict most other findings on the amygdala in adult and child samples. The small sample size, mixed anxiety disorder sample, and/or disorder severity of the sample (children with anxiety disorders were classified as "treatment-resistant") may have led to the contradictory findings. Nevertheless, given how little research has been conducted to date in child samples, as well as the fact that most studies have relatively small sample sizes, additional research is needed to resolve the contradictory findings.

Adding to these findings on amygdala volume differences, functional imaging studies have consistently found that the amygdala and associated regions are activated during fear conditioning experiments in animals (LeDoux, 1998, 2000) and in healthy adults (Büchel & Dolan, 2000; LaBar, Gatenby, Gore, LeDoux, & Phelps, 1998; Schneider et al., 1999). Furthermore, fMRI studies using face processing paradigms show preferential activation of the amygdala and related structures in response to fearful versus neutral or happy faces in normal adults (Breiter et al., 1996; Morris et al., 1996), and the amygdala and associated regions demonstrate more activity in individuals with anxiety disorders than in individuals without anxiety disorders upon exposure to feared stimuli (Nitschke et al., 2009). According to Craske, Rauch, and colleagues (2009), the amygdala plays an important role in the assessment of threat, as well as in the formation of associations regarding danger in the environment and mediation of responses to threat. They suggest that exaggerated sensitivity of the amygdala mediates abnormal threat assessment, abnormalities in learning about danger in the environment, and/or exaggerated fear responses. For instance, when viewing masked angry faces, children with GAD showed greater right amygdala activation than healthy controls did, and this activation was positively correlated with anxiety severity (Monk et al., 2008). Likewise, when viewing fearful expressions, adolescents with GAD showed increased right amygdala responses, par-

ticularly when they rated subjective degrees of internal fear (McClure et al., 2007). In another study of socially anxious adolescents, using anticipation of peer evaluation within a simulated Internet chat room, Guyer, Lau, and colleagues (2008) found that anxious adolescents showed greater amygdala activation than did healthy adolescents when viewing photographs of peers rated as less desirable relative to those deemed more desirable for an anticipated social interaction. Similarly, in a study of adolescents temperamentally at risk for anxiety, exaggerated amygdala response was detected among behaviorally inhibited adolescents when they were viewing emotional faces while providing subjective fear ratings (Pérez-Edgar et al., 2007). However, in this same study, compared with noninhibited adolescents, inhibited adolescents showed deactivation of the amygdala during passive viewing of emotional faces, suggesting that attention state may alter the underlying pattern of neural processing. On the other hand, in a study of healthy adolescents and adults, during passive viewing of fearful faces, adolescents demonstrated greater amygdala and fusiform activation than did adults (Guyer, Monk, et al., 2008).

Research has also found differences in amygdala functioning among children with anxiety disorders and depression. Thomas and colleagues (2001) found enhanced amygdala activation during viewing of emotional faces among children and adolescents with anxiety disorders, whereas children and adolescents with depression showed blunted amygdala response during viewing of emotional faces. Crossing attention to emotional faces with anxiety and depression, Beesdo, Lau, and colleagues (2009) found an even more complex interaction. Specifically, they found that when adolescents viewed fearful faces and focused their attention on internally experienced fear (vs. passive viewing), individuals with anxiety disorders and major depressive disorder showed greater amygdala activation than their healthy peers. However, when passively viewing fearful faces, the anxious adolescents demonstrated amygdala hyperactivation relative to their healthy peers, and the depressed adolescents demonstrated amygdala hypoactivation relative to their healthy peers. Thus it appears that disorder-specific biases emerge under unconstrained attention conditions.

BED NUCLEUS OF THE STRIA TERMINALIS

Complicating things further, whereas the amygdala appears to be consistently involved in short-term responses to threatening stimuli, the bed nucleus of the stria terminalis (BNST) has a slower response but continues to influence behavior long after the initiating stimulus has been terminated. The BNST is a region of the extended amygdala complex (Walker & Davis, 2008), and the pattern of connectivity in the BNST suggests that this region acts as a relay center coordinating the activity of autonomic, neuroendocrine, and somatic motor systems into fully organized physiological functions and behavior (Dumont, 2009). The BNST may be at least partially under the control of the medial PFC (Spencer, Buller, & Day, 2005), and it appears that it may receive emotional and learning associated information and may be involved in integrating these inputs with reward/motivational circuits (Jalabert, Aston-Jones, Herzog, Manzoni, & Georges, 2009). In a study of adults with GAD who engaged in a task with high uncertainty, adults with GAD demonstrated decreased activity in the amygdala and increased activity in the BNST (Yassa, Hazlett, Stark, & Hoehn-Saric, 2012). Thus whereas the amygdala may play a role in immediate threat-related situations, the BNST may take over in longer-term stress-related situations. This may in part explain some of the contradictory findings related to amygdala functioning described above. However, more research is needed, especially in child samples.

HIPPOCAMPUS AND PREFRONTAL CORTEX

Two other important structures that interact with the amygdala in fear-related processing are the hippocampus and the PFC. The hippocampus is adjacent to the amygdala in the limbic system and is associated with conversion of short-term into long-term memories, whereas the PFC is located on the anterior part of the frontal lobes and is associated with executive functioning. According to Craske, Rauch, and colleagues (2009), the ventromedial PFC and hippocampus supply top-down control over the amygdala. On extinction recall tasks, individuals first participate in fear conditioning (pairing a neutral stimulus with a fearful stimulus), and then they are subsequently tested during extinction (presentation of the neutral stimulus alone). During extinction recall, the ventromedial PFC controls the amygdala by inhibiting responses to learned threat cues. Furthermore, the hippocampus supplies information that is permissive of extinction recall by providing information regarding safe versus dangerous contexts. Thus, since the hippocampus and PFC share reciprocal projections with the amygdala, through which it

can modulate PFC neuronal activity and the PFC can modulate amygdala-mediated responses to emotionally salient stimuli (Garcia, Vouimba, Baudry, & Thompson, 1999; Quirk, Russo, Barron, & Lebron, 2000), these areas have been implicated in extinction learning. In contrast to fear acquisition, extinction learning involves modulation of lateral amygdala neuron activity through excitatory inputs from the ventromedial PFC onto inhibitory intra-amygdala interneurons (Quirk & Mueller, 2007). Interestingly, it appears that there may be greater connectivity between the amygdala and the hippocampus in adults than in adolescents. As described above, Guyer, Monk, and colleagues (2008) found greater amygdala activation and connectivity between the amygdala and hippocampus among healthy adolescents than adults during passive viewing of fearful faces. They interpreted this finding as evidence of maturation in learning or habituation to facial expressions in adults.

Regarding the PFC, research in adults has found that adults with GAD show increased amygdala connectivity with different PFC regions, such as the dorsomedial and ventromedial PFC, compared with healthy controls (Etkin, Prater, Schatzberg, Menon, & Greicius, 2009). In the Monk and colleagues (2008) studies described above, children with GAD showed strong right amygdala and right ventrolateral PFC coupling when viewing masked angry faces, suggesting that the PFC modulates the amygdala response to threat. Likewise, in the study of socially anxious adolescents described above, Guyer, Lau, and colleagues (2008) found coactivation in the amygdala and ventrolateral PFC circuitry when participants were viewing photographs of peers for an anticipated social interaction. The PFC has also been implicated in studies of healthy children and adolescents (Telzer et al., 2008) and in adolescents with GAD (McClure et al., 2007; Monk et al., 2006) during attentional bias tasks for angry faces.

The OFC is part of the PFC and is involved in decision making and guiding behavior; it seems to be particularly important in signaling the expected rewards or punishers of a planned action. According to Craske, Rauch, and colleagues (2009), the medial OFC mediates positive valuations (e.g., of reward and safety), whereas the lateral OFC mediates negative valuations (e.g., of punishment); thus medial OFC plays a role in suppression of fear, whereas lateral OFC appears to mediate negative cognitions such as obsessions and worry. Although increased activation within lateral OFC has not been consistent across anxiety disorders, it may be a hallmark function of conditions characterized by worry and obsessions (Milad & Rauch, 2007). Consistent with this finding in adults, adolescents with GAD, SOC, and SAD show significantly enhanced left OFC activation relative to healthy controls (Beesdo, Lau, et al., 2009).

INSULAR CORTEX AND ANTERIOR CINGULATE CORTEX

In addition to the PFC, two other regions of the cortex are implicated in the anxiety disorders; however, there is little research on these regions in children and adolescents. The ACC is located in the front of the cingulate cortex around the corpus callosum. The ACC has two components—the dorsal ACC and the ventral ACC. The dorsal ACC is sometimes referred to as the "cognitive component," as it is connected to the PFC and has been implicated in functions such as error detection, conflict monitoring, and attention; the ventral ACC is sometimes referred as the "affective component," because it is connected to the amygdala, nucleus accumbens, hypothalamus, and anterior insula and is involved in assessing the salience of motivation and emotion (Craske, Rauch, et al., 2009). The ACC appears to play a role in disorders characterized by pathological doubting, such as obsessive–compulsive disorder (formerly classified with the anxiety disorders) and GAD, because it plays a role in suppressing attention and response to cognitive (dorsal ACC) and affective (ventral ACC) stimuli. Although the research on pediatric samples is limited, the study by McClure and colleagues (2007) described above suggests that in addition to the amygdala and PFC, the ACC also plays a role in adolescent GAD.

The insular cortex (insula) is a portion of the cerebral cortex folded within the lateral sulcus (separating the temporal and parietal lobes). According to Craske, Rauch, and colleagues (2009), it mediates interoception and thus plays a role in awareness of and sensitivity to visceral activity. Given that stronger physiological responses to aversive stimuli elicit stronger classical conditioning, the insula is implicated in anxiety sensitivity, or fearfulness of the potentially harmful nature of the cognitive and behavioral correlates of anxiety (Reiss & McNally, 1985; Reiss et al., 1986). In a meta-analysis, Etkin and Wager (2007) found that adults with SOC, specific phobia, or posttraumatic stress disorder showed greater activity than comparison adults in the amygdala and insula, and a similar pattern was observed during fear conditioning in healthy participants. Interestingly,

hyperactivation in the amygdala and insula were more frequently observed with SOC and specific phobia than with posttraumatic stress disorder. To our awareness, no studies have examined the insula in child samples.

STRIATUM

The final set of neural circuitry that has been examined with regard to anxiety disorders is the striatum, which includes the nucleus accumbens, the putamen, and the caudate nucleus. These structures are located in the basal ganglia at the base of the forebrain and are involved in responding to reward-related cues. In studies of adolescents, those who had been classified as behaviorally inhibited in early childhood showed increased activation in the striatum, compared with adolescents classified as noninhibited in early childhood, while anticipating monetary gain or loss (Bar-Haim et al., 2009; Guyer et al., 2006). In a study of adolescents with anxiety disorders, while anticipating incentives of increasing magnitude, adolescents with SOC showed increasingly heightened caudate and putamen activation relative to that seen in the healthy comparison group and the group with GAD (Guyer et al., 2012). Thus it appears that, similar to findings in behaviorally inhibited adolescents, adolescents with SOC show similar neural responses in anticipation of incentives.

In summary, it appears that a number of neural circuits are involved in the anxiety disorders, including the amygdala, PFC, hippocampus, OFC, ACC, insular cortex, and striatum. The extent to which these regions are also affected in pediatric anxiety disorders has yet to be fully explored. Of the limited research to date that has been conducted on child and adolescent samples, most has focused almost exclusively on adolescents with GAD, and the sample sizes have been relatively small (N's < 20). Additional research in this area is needed and is likely to characterize the next decade of research on the psychopathology of the anxiety disorders in childhood.

Glucocorticoid Neurohormones (Cortisol)

In addition to examining brain structure and functioning, study of the neurobiology of stress and anxiety has focused on how the endocrine system functions in response to stress. The endocrine system uses hormones to send messages to the bodily organs, which are produced by several glands throughout the body. Cortisol, which is released by the hypothalamic–pituitary–adrenocortical (HPA) axis, is the most commonly studied stress hormone. The HPA axis is a complex chain of influences and feedback interactions between the hypothalamus (located in the midbrain), the pituitary gland (base of the brain), and the adrenal glands (on top of the kidneys). The hypothalamus releases corticotropin-releasing hormone (CRH) when the body is stressed. CRH then stimulates the pituitary gland to release adrenocorticotropic hormone (ACTH), which in turn stimulates the adrenal glands to release glucocorticoid hormones (or cortisol). Cortisol in turn acts on the hypothalamus and pituitary to suppress CRH and ACTH in a negative feedback loop. Although typically following a 24-hour circadian pattern, cortisol is secreted at increased levels during periods of heightened stress (Kirschbaum, Pirke, & Hellhammer, 1993).

Increases in cortisol have both immediate and delayed negative effects on various aspects of functioning. In the short term, cortisol can interfere with communication between different brain structures and can temporarily impair attentional and memory processes (Davis, Bruce, & Gunnar, 2002). Sustained increases in cortisol (e.g., in response to chronic stressors), however, have been associated with more detrimental outcomes, including anxiety disorders (e.g., Forbes et al., 2006; Granger, Weisz, & Kauneckis, 1994; Kallen et al., 2008). For instance, in a study of children with SAD (mean age = 8.45 years), these children showed higher cortisol secretion than did controls across the entire duration of the investigation, and their cortisol secretion increased when they anticipated being separated from a parent (Brand, Wilhelm, Kossowsky, Holsboer-Trachsler, & Schneider, 2011). Similarly, in a study of children with SOC (ages 6–12), these children showed elevated cortisol response compared with healthy controls during a public speaking task (van West, Claes, Sulon, & Deboutte, 2008). Furthermore, persistence of anxiety disorders is associated with changes in cortisol production. In a recent study of children with anxiety disorders receiving cognitive-behavioral treatment, persistence of anxiety disorders after treatment was related to increased daytime cortisol production; at a 1-year follow-up, daytime cortisol was lowest in the early remitters, higher in the late remitters, and highest in the nonremitters (Dierckx et al., 2012). In this study, remission status was also related to morning cortisol rise. Normal HPA axis functioning is associated with a rapid early morning rise in cortisol production; however, the nonremitters had the lowest cortisol morning

rise, compared with early remitters and late remitters (Dierckx et al., 2012). These findings suggest not only that anxiety disorders are associated with higher overall levels of cortisol, but that there appears to be a dysregulation of the HPA axis among those with persistent anxiety problems.

In fact, some research shows that although transient stressors result in increased cortisol secretion, chronic stress is associated with blunted cortisol secretion (Marin, Martin, Blackwell, Stetler, & Miller, 2007; Miller, Chen, & Zhou, 2007). In a meta-analysis of 107 studies, Miller and colleagues (2007) found that effects on the HPA axis depend on the features of the stress. In particular, it appears that both recent stress and ongoing stress are associated with increased HPA output, whereas distant traumas are associated with decreased HPA output to below normal levels, suggesting a down-regulation of the HPA axis. Miller and colleagues (2007) also found that stress that threatens physical integrity (e.g., combat, child abuse), as well as uncontrollable stress, elicits a slightly lower morning secretion with higher afternoon/evening and evening output. Consistent with this meta-analysis (which focused on studies with adults), a recent longitudinal study of 96 adolescents found that those with more internalizing problems in adolescence had higher morning cortisol; however, when the sample was examined longitudinally, those who had greater internalizing behaviors in childhood had lower morning cortisol levels as adolescents (Ruttle et al., 2011). Thus it appears that whereas the HPA axis is activated when children first display behaviors, long-term exposure may lead to dysregulation of the HPA axis over time.

Chronic or prolonged exposure to heightened levels of cortisol as a result of early stress or trauma also appears to have neurotoxic effects on the developing brain (Lupien, McEwen, Gunnar, & Heim, 2009; Sapolsky, Krey, & McEwen, 1986). Lupien and colleagues (2009) suggest that the specific effect of chronic stress on the developing brain is a result of the time at which the stress occurs during critical brain development periods. In other words, the effects of cortisol (as a result of prolonged or chronic stress) have the highest impact on the brain structures that are developing at the time of the stress. For example, it appears that stress and heightened glucocorticoids experienced during childhood may have a greater impact on the hippocampus, which is continuing to develop in childhood. On the other hand, the critical development period for the PFC is in adolescence, and thus chronic stress at this time appears to have a greater effect on the development and functioning of this structure (Lupien et al., 2009).

Temperament

An accumulation of findings over the last half century suggests that child temperament may be a general vulnerability factor for anxiety. *Temperament* generally refers to inherent basic dispositions, which underlie and modulate expressions of emotionality, activity, and sociability (Buss & Plomin, 1975, 1984; Thomas & Chess, 1985). Most research suggests that temperament is evident early in life, is strongly biologically based, and is generally stable throughout life (Buss & Plomin, 1984; Derryberry & Rothbart, 1984; Rothbart, 1989). Temperament is often considered an early form of personality, and accordingly, several studies have examined the relation among common temperamental factors and the Big Five model of personality (Angleitner & Ostendorf, 1994; Digman, 1994). For instance, in a sample of 624 children ages 6 to 7 in the People's Republic of China and the United States, Ahadi, Rothbart, and Ye (1993) found three temperamental factors that emerged on the Children's Behavior Questionnaire, a parent report measure of child temperament. The three basic temperament factors that emerged across the two cultures are consistent with three of the Big Five: Extraversion (Surgency), Neuroticism (Negative Affectivity/Emotional Stability), and Conscientiousness (Effortful Control).

The Tripartite Model of Emotion

Perhaps the greatest accumulation of recent research in this area builds on Clark and Watson's (1991) tripartite model of emotion and its relation to anxiety and depression in children (see also Mineka, Watson, & Clark, 1998). The tripartite model originally posited factors of Positive Affectivity (PA), Negative Affectivity (NA), and Physiological Hyperarousal (PH), to account for the relation of anxiety and depression (with PA and NA likened to Extraversion and Neuroticism, respectively; e.g., Ahadi et al., 1993; Lonigan & Phillips, 2001). Clark and Watson (1991) articulated a model in which NA represented a factor common to anxiety and depression, (low) PA represented a factor specific to depression, and PH represented a factor specific to anxiety. Considerable evidence has shown that both NA and PA appear to be temperamental constructs, acting as risk factors for anxiety and mood disorders (e.g., Lo-

nigan & Phillips, 2001; Mineka et al., 1998; Watson, Clark, & Harkness, 1994).

Given the implications of this model for understanding both the etiology and comorbidity of anxiety and depression, there have been ongoing efforts to investigate the validity of the tripartite model of emotion in child and adolescent samples (e.g., Chorpita, 2002; Chorpita, Albano, & Barlow, 1998; Joiner et al., 1996; Lonigan et al., 1994; Lonigan, Hooe, David, & Kistner, 1999; Lonigan, Phillips, & Hooe, 2003). The collective findings support a model in children and adolescents roughly consistent with the tripartite model in adults (e.g., Chorpita, Albano, & Barlow, 1998; Joiner et al., 1996). For example, Lonigan and colleagues (1994) found that measures related to low PA best discriminated children with depressive disorders from those with anxiety disorders. Lonigan and colleagues (1999) examined the relations of PA and NA measures with anxiety and depression measures in a school sample of 365 children and adolescents and found that NA and PA measures performed in a manner consistent with findings from adult samples, and that such findings were uniform across children and adolescents. Furthermore, Lonigan and colleagues (2003) found temporal stability of a two-factor orthogonal model of NA and PA in a longitudinal study of 4th- to 11th-grade children; this model predicted symptoms of anxiety and depression, providing additional support for the notion that NA and PA are temperamental factors.

Amidst a gathering of empirical support for the tripartite model, some revisions to the model in the late 1990s (Brown et al., 1998; Mineka et al., 1998) suggested that PH is not uniformly related to all anxiety disorders. For example, in a sample of 350 adults with anxiety disorders, Brown and colleagues (1998) found that PH was related positively only to measures of panic, but not to the other anxiety disorders measured. These results were first partially replicated in a sample of 100 children with anxiety and mood disorders (Chorpita, Plummer, & Moffitt, 2000). As had been done in previous studies in the child literature, tripartite scales were constructed by summing items from anxiety and depression measures that were selected to represent the constructs of NA, PA, and PH. Although consistencies with findings in the adult literature were enough to encourage continued research, the number of inconsistencies raised some questions about the utility of these early measurement strategies (Lonigan et al., 1999). The model outlined by Brown and colleagues in adults was therefore evaluated once more in a nonclinical sample of 1,578 children in grades 3 through 12, using a measure empirically designed to tap the tripartite factors in children (Chorpita, 2002). The results of that investigation were consistent with previous observations in adult samples; in particular, PH was positively related with panic only, and was not significantly positively correlated with other anxiety dimensions. The model also appeared robust across different grade levels and gender (Chorpita, 2002).

One particularly interesting feature in this line of investigation is that the relation between the general vulnerabilities in the model (i.e., NA) and generalized anxiety measures tend to be among the strongest links. In fact, early research in this area frequently used items taken from older measures of anxiety as indicators for NA, and a diversity of findings suggests that many of the early anxiety measures may actually have been better characterized as measures of a broad negative emotionality (Stark & Laurent, 2001). The similarity between NA and the general experience of anxious emotion has been raised elsewhere (Chorpita & Barlow, 1998); in the context of anxiety and depressive disorders, it suggests that anxiety itself may represent a risk factor for the development of anxiety disorders as well as depression. This notion is consistent with many of the patterns found in adult research, such as the tendency for the onset of anxiety disorders to precede depression but not the reverse, as well as observations of asymmetrical comorbidity (whereby anxiety disorders often co-occur with cases of depression, but depression co-occurs less frequently with cases of anxiety disorders). Findings in the child literature lend further support to this idea. In a prospective study of 330 children followed over a 3-year period, heightened anxiety symptoms predicted future high depression even after adjustments for past depression scores, but the reverse was not found (Cole, Peeke, Martin, Truglio, & Ceroczynski, 1998).

Despite growing empirical support for the applicability of the tripartite model to younger child samples, there is stronger support for its applicability in samples of older children and adolescents. For example, Jacques and Mash (2004) found that among a large community sample of elementary school children and high school adolescents ($N = 472$), the tripartite model was better supported in the older sample. Similarly, Lonigan and colleagues (1999) found that the tripartite model fit data from older children from a nonclinical sample ($N = 213$, ages 12–17) better than their younger counterparts ($N = 152$, ages 9–11). Moreover, in a recent multisample confirmatory factor-analytic study of 1,470 clinic-referred

and 757 school-based children (ages 7–18), Price and colleagues (2013) found support for separating anxiety and depression for all samples except for the nonclinical younger sample, suggesting that these constructs are more similar than different in subclinical children. Results from these studies support the notion that there is an underlying trait contributing to both anxiety and depression (i.e., NA), and that differentiation between anxiety and depression increases across development (De Bolle & De Fruyt, 2010).

Behavioral Inhibition

A classic model of temperament and its relation to anxiety involves the work of Kagan and colleagues regarding behavioral inhibition (BI; e.g., Biederman et al., 1990, 1993a, 1993b; Hirshfeld et al., 1992; Kagan, 1989, 1997; Rosenbaum et al., 1988, 1992; Rosenbaum, Biederman, Hirshfeld, Bolduc, & Chaloff, 1991). As defined by Kagan (1989, 1997), BI refers to a child's degree of sociability and degree of uncertainty toward novel objects, situations, and people, as displayed by observable behaviors manifested along the approach–withdrawal dimension. The criteria by which BI is measured include both behavior (speech latency and frequency to peers and adults, proximity to caregiver, physical inactivity, verbalization of distress) and physiology (heart rate, heart rate variability, blood pressure, pupil dilation, muscle tension, cortisol level, urinary norepinephrine levels, and vocal pitch) (Kagan, Reznick, Snidman, Gibbons, & Johnson, 1988). Children with consistent BI across time have been found to evidence greater autonomic reactivity, elevated morning cortisol levels, heightened startle responses, and more vigilant attention styles (Pérez-Edgar & Fox, 2005; Schmidt & Fox, 1998; Schmidt, Fox, Schulkin, & Gold, 1999). Functional imaging studies have also found those with BI to display heightened amygdala activation to novel neutral or threatening faces (Perez-Edgar et al., 2007; Schwartz, Wright, Shin, Kagan, & Rauch, 2003).

Approximately 15% of children are characterized as displaying BI across samples (Fox et al., 2005; Kagan, Reznick, Snidman, Gibbons, & Johnson, 1988). According to Kagan, Reznick, Snidman, Gibbons, and Johnson (1988), these children become shy and fearful as toddlers, and quiet, cautious, and introverted by the start of their primary school years. In standardized behavioral test situations, these children consistently refrain from spontaneous vocalizations when in the presence of a stranger, and cry and cling to their mothers rather than explore play settings and approach other children. At the other end of the scale, about 15% of the children studied demonstrated an opposing temperament of being sociable, bold, and gregarious. Moreover, as opposed to the inhibited cohort, these uninhibited children are untroubled by novel stimuli. Kagan and colleagues have followed two independent cohorts of children over an extended (7-year) period. Children were originally identified as inhibited or uninhibited at either 21 or 31 months of age during standardized behavioral tests when exposed to unfamiliar settings, people, and objects. These differences in behavior were largely maintained through repeated assessments at 4, 5, and 7 years of age, suggesting that such differences represent an enduring temperamental trait (see Kagan, Reznick, & Gibbons, 1989). Thus BI appears to be biologically based, is detectable early in life, is moderately stable across life, and appears to be under some genetic control (Kagan, Reznick, & Snidman, 1988; Robinson, Kagan, Reznick, & Corley, 1992; Smoller et al., 2003, 2005).

Kagan's original work on BI was designed to examine temperamental styles of infants, and thus no specific hypotheses regarding psychopathology were postulated. However, as attention turned toward the study of childhood anxiety disorders, the similarities between inhibited and anxious children became more apparent. In a recent review of the literature on BI and child anxiety, Degnan, Almas, and Fox (2010) reviewed more than 30 different studies that examined the relation between BI and child anxiety. In general, the research supports concurrent and longitudinal relations between BI and child anxiety. For instance, early childhood BI is significantly related to later diagnosis and symptoms of anxiety (e.g., Biederman et al., 1990; Hirshfield et al., 1992; Hirshfeld-Becker et al., 2007; van Brakel, Muris, Bögels, & Thomassen, 2006). Furthermore, Hudson and Dodd (2012) recently found that BI at age 4 was associated with increased risk for SOC, SAD, and GAD at age 9. Support for BI as a risk factor for SOC has been replicated in a number of different studies, suggesting that BI may share a uniquely strong relation with SOC above and beyond the other anxiety disorders (Biederman et al., 2001; Chronis-Tuscano et al., 2009; Essex, Klein, Slattery, Goldsmith, & Kalin, 2010; Muris, van Brakel, Arntz, & Schouten, 2011; Schwartz, Snidman, & Kagan, 1999).

Despite such apparent associations, however, at least a quarter of children identified as displaying BI do not

show any diagnosable anxiety disorder (e.g., Biederman et al., 2001; Gladstone, Parker, Mitchell, Wilhelm, & Malhi, 2005). Furthermore, at least one study has failed to show that children characterized as exhibiting extremely high BI at age 3 were at increased risk for anxiety disorders at age 21. Instead, these children were found to be at increased risk for depression at age 21 (Caspi et al., 2003). Thus, although BI is one of the most consistent individual risk factors for later anxiety (Fox et al., 2005; Mian, Wainwright, Briggs-Gowan, & Carter, 2011), the association between childhood BI and later anxiety still shows almost as much disassociation as it shows association across time (Degnan & Fox, 2007); this suggests that there are other risk factors that may interact with temperament across development (Hudson & Dodd, 2012; Muris et al., 2011).

The Behavioral Inhibition System

Whereas Kagan's work on BI has focused primarily on behavioral and physiological outputs of temperament, and specifically within a social context, other models of temperament and anxiety have focused more directly on the organization of biological systems that underlie motivation and emotion more generally (e.g., Gray & McNaughton, 1996). Gray (1982) detailed the operations of two functional brain systems that serve to motivate behavior—the behavioral inhibition system (BIS) and the behavioral activation system (BAS). Both systems function independently in typical individuals and are sensitive to different types of reinforcement. The BAS is sensitive to signals of reward and absence of punishment, and behavioral effects include appetitive approach behavior. On the other hand, the BIS is sensitive to signals of punishment, nonreward, and novelty. Behavioral effects of the BIS include inhibition of ongoing behavior, increased attention, and increased arousal. According to Gray, the primary, short-term outputs of the BIS involve narrowing of attention, inhibition of gross motor behavior, increased stimulus analysis (e.g., vigilance or scanning), increased central nervous system arousal (e.g., alertness), and priming of hypothalamic motor systems for possible rapid action that may be required (i.e., possible activation of the fight–flight system). Its phenomenology is characterized by increased caution, vigilance, and processing of threat-relevant information. In a study of 170 children ages 3–5, parent-reported withdrawal motivation (BIS) was associated with cortisol increase, whereas parent-reported approach motivation (BAS) was associated with cortisol decrease (Blair, Peters, & Granger, 2004).

Similar to research on the tripartite model, some work on Gray's model suggests that there may be a third system—the fight–flight–freeze system (FFFS; Gray & McNaughton, 2000), which is activated by aversive stimuli and motivates escape behavior. Overactivity in BIS is assumed to be an underlying factor across all anxiety disorders, whereas overactivity in FFFS is assumed to be related to panic disorder, SOC, and specific phobia (Gray & McNaughton, 2000; Zinbarg & Yoon, 2008). For instance, in a study of 175 clinically anxious and nonanxious children ages 8–18, Vervoort and colleagues (2010) found that BIS scores were highest among those with anxiety disorders; the BIS_Anxiety scale was significantly correlated with all subscales on a brief measure of anxiety disorder symptoms, whereas the BIS_FFFS scale was only significantly related to the panic and social anxiety subscales of this measure.

Effortful Control

Another temperamental trait that is garnering attention for its potential contribution to the development of anxiety is effortful control (EC), or the ability to engage executive functioning processes to inhibit reactive tendencies and substitute more adaptive responses (Derryberry & Rothbart, 1997; Lonigan & Phillips, 2001; Lonigan & Vasey, 2009; Posner & Rothbart, 2000). According to Lonigan and Phillips (2001), although high NA accounts for some of the variance observed in the development of anxiety disorders, there are potential moderators to consider, given that not everyone with high NA develops an anxiety disorder. Lonigan and Phillips suggest that the combined effects of high NA and low EC are required for the development of anxiety disorders, and some cross-sectional and longitudinal research has supported this theory. For instance, in two separate studies of children and adolescents, Muris and colleagues found that EC moderated the relation between NA and internalizing symptoms (Muris, 2006; Muris, Meesters, & Rompelberg, 2007), and in a study of 10-year-old children, EC and NA interacted to predict internalizing symptoms over a 3-year period (Oldehinkel, Hartman, Ferdinand, Verhulst, & Ormel, 2007). Thus, although temperament clearly plays a role in the development of anxiety disorders, the nature of this contribution appears to go beyond rudimentary main effects of common temperamental dimensions.

Cognitive and Learning Influences

In light of the review above, it is clear that any psychosocial influences might better be considered biopsychosocial in nature, given their important dynamic interaction with aspects of biology and temperament. In addition, more recent theorizing suggests that just as the general biological influences for anxiety overlap heavily with those for depression, so too do the general psychological influences for anxiety. Within this context, recent work has focused on detailing possible mechanisms or processes that may establish or intensify risk for negative emotions, especially regarding cognitive coping strategies (Kendall, 1992), information processing (McNally, 1996; Vasey, Daleiden, Williams, & Brown, 1995), social–familial transmission (Barrett, Rapee, Dadds, & Ryan, 1996; Chorpita, Brown, & Barlow, 1998), and complex forms of conditioning (Bouton, Mineka, & Barlow, 2001).

Information Processing

Early cognitive models of child anxiety were drawn largely from Beck's schema-based theory of adult anxiety (Beck, Emery, & Greenberg, 1985). Schemas are organized bodies of information stored in memory, which facilitate the processing of information that is consistent with the schemas and interfere with information that is inconsistent with them. In 1990, Kendall and Ronan proposed that childhood anxiety is a result of overactivity of threat-related schemas. Not long after, Daleiden and Vasey (1997) adapted Crick and Dodge's (1994) stage model of information processing in aggressive children to outline a more precise role of cognitions in child anxiety. There are six stages in the model: (1) *encoding*, in which information is selected for further processing; (2) *interpretation*, in which meaning is attached to ambiguous information and causal attributions, and outcome expectations are made; (3) *goal clarification or selection*, in which goals are revised and selected to meet the demands of the situation; (4) *response access or construction*, in which potential responses are retrieved or generated; (5) *response selection*, in which potential responses are evaluated; and (6) *enactment*, in which the best possible response is selected and enacted. Furthermore, memory is believed to influence every stage of the process, affecting both the content and the organization of information. Whereas the first two stages have garnered a wealth of support in the research over the last two decades, the third through sixth stages have not been as well studied; nor has memory processing been widely studied.

SELECTIVE ATTENTION

According to information-processing theories of anxiety (Beck et al., 1985; Daleiden & Vasey, 1997; Kendall & Ronan, 1990), children with heightened anxiety should selectively attend to threatening over nonthreatening information. In other words, they should demonstrate an attentional bias toward threat. In a meta-analysis, Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, and van IJzendoorn (2007) found a medium effect (d = 0.45) for threat-related attentional biases across all experimental paradigms, conditions, and populations, with studies of children (k = 11) also showing a medium effect (d = 0.50).

Two experimental paradigms have been widely studied in the child anxiety information-processing literature to date: a modified emotional Stroop task and a dot probe task. In the emotional Stroop task, participants are told to name the color of the ink a word or picture is printed in. Words or pictures are then varied, typically falling into threatening and nonthreatening/neutral categories. For instance, in studies assessing attentional bias among children with spider phobia, words such as "spider" or "crawling" would be considered threatening stimuli, whereas words such as "fence" or "grass" would be regarded as nonthreatening stimuli. Because threat-relevant words have captured the child's attention (bias toward threat), anxious children are expected to take longer to name the color of those words relative to the neutral words. Although findings using the modified Stroop task among children with heightened anxiety have not been completely consistent, the Bar-Haim and colleagues (2007) meta-analysis reported that across studies, anxious children were typically slower than controls to respond to threat words, and the differences between threat and nonthreat words were more pronounced in anxious children relative to controls.

On the other hand, Bar-Haim and colleagues (2007) found no difference between anxious and nonanxious control children in attentional bias on dot probe tasks. This is somewhat surprising, given earlier research suggesting that anxious children do evidence an attentional bias toward threat with this experimental paradigm (e.g., Vasey et al., 1995; Vasey, El-Hag, & Daleiden, 1996). In a dot probe task, children view two words or stimuli on a computer screen, one on top of

the other. Some trials pair a threatening and a nonthreatening stimulus at the same time on the screen, and in some trials the pairing is neutral–neutral. Immediately following the presentation of these stimuli, a small dot probe appears in the position previously occupied by one of the two words (randomly alternating across threatening and neutral positions). Children are instructed to respond when they see the dot probe appear (e.g., to press a button on a keyboard). The latency to detect this probe measures attention toward the word that just appeared within the probed screen location. Thus shorter latencies when the probe follows a threat word indicate attentional bias toward the threat word. One potential methodological explanation for Bar-Haim and colleagues' finding is that the Vasey and colleagues (1996) study was not included in that meta-analysis because it was a significant outlier.

INTERPRETATION BIAS

In addition to attending selectively to threatening over nonthreatening information, anxious children demonstrate clear interpretation biases. Research has generally demonstrated that across experimental paradigms, anxious children perceive more threat, perceive threat more quickly, make more threatening interpretations and predictions when presented with ambiguous situations, and select more threatening interpretations on homophone tasks (Barrett, Rapee, et al., 1996; Bell-Dolan, 1995; Cannon & Weems, 2010; Chorpita, Albano, & Barlow, 1996; Epkins, 1996; Hadwin, Frost, French, & Richards, 1997; Higa & Daleiden, 2008; Micco & Ehrenreich, 2008; Muris, Merckelbach, & Damsma, 2000; Taghavi, Moradi, Neshat-Doost, Yule, & Dalgleish, 2000; Weems, Berman, Silverman, & Saavedra, 2001; Weems, Costa, Watts, Taylor, & Cannon, 2007). Moreover, anxious children make more internal, stable, and global attributions for negative events than nonanxious controls do (Bell-Dolan & Last, 1990), and they tend to expect catastrophic outcomes, underestimate the future likelihood of positive outcomes, and have lower coping expectations (Chorpita et al., 1996; Micco & Ehrenreich, 2008; Leitenberg, Yost, & Carroll-Wilson, 1986; Spence et al., 1999). Nevertheless, not all studies have found support for interpretation biases (e.g., Bögels & Zigterman, 2000; In-Albon, Dubi, Rapee, & Schneider, 2009); the content specificity for interpretation biases has not been established (Bögels, Snieder, & Kindt, 2003; Dalgleish et al., 2003; Muris, Merckelbach, & Damsma, 2000); and at least one study has found that after adjustments for depressive symptoms, the relation between negative interpretations and anxiety symptoms was no longer significant (Eley, Gregory, et al., 2008). Thus, similar to research on selective attention, interpretation biases among anxious children appear to be less robust than those found among anxious adults or those the original theories would suggest. Therefore, some researchers have begun to question the downward extension of adult cognitive models to children.

DEVELOPMENT AND INFORMATION-PROCESSING BIASES IN CHILDREN

In a recent review, Field and Lester (2010) discuss two competing models that take development into account and compare these with the downward extension of cognitive theories in adults. In the first moderational model, Field and Lester suggest that information-processing biases may be present in all young children (anxious and nonanxious)—perhaps serving an evolutionary function—and that these biases diminish over time as a result of experiences with the environment for most children, but remain for those predisposed to anxiety. In other words, bias toward threatening information is a normal developmental process that decreases over time in typical individuals; however, those with a predisposition to anxiety do not learn to ignore or do not develop the ability to inhibit attention to threat, which makes them more vulnerable to biases in information processing (Kindt & van den Hout, 2001; Nightingale, Field, & Kindt, 2010). Research indicates that infants as young as 5 months of age and pre-school-age children show attentional biases to fear-relevant stimuli, including spiders, snakes, and angry faces (LoBue & DeLoache, 2008, 2010; Rakison & Derringer, 2008), and Creswell and colleagues (2008) found no differences between behaviorally inhibited and uninhibited infants' look times at angry, happy, and fearful faces. Furthermore, this model fits with attentional bias studies that have found no differences in anxious and nonanxious children under age 12 (e.g., Kindt, Bierman, & Brosschot, 1997; Kindt, van den Hout, de Jong, & Hoekzema, 2000; Waters, Lipp, & Spence, 2004).

In another attempt to explain some of the null findings in selective attention tasks, Lonigan and Vasey (2009) studied the moderating effects of EC on the relation between NA and attentional biases. They found that among children and adolescents, those who were high in NA and low in EC demonstrated significant

bias in favor of threat cues, whereas those high in NA and high in EC did not show this bias. Furthermore, although they did not find an age effect (which calls the moderational model into question), the youngest participants in their study were 10 years of age, which is the age above which some research has suggested that such biases tend to diminish among nonanxious children (Kindt et al., 2000). Taken together, these studies suggest the possibility that the capacity for effortful control develops around the same time that attentional biases diminish among nonanxious children (e.g., Posner & Rothbart, 2000), and thus both could be playing a role in the development of attentional biases among anxious children.

Field and Lester's (2010) second competing model appears to have more relevance for understanding interpretation biases. The acquisition model, which has also been described by other researchers (Alfano, Beidel, & Turner, 2002; Manassis & Bradley, 1994), suggests that the emergence of information-processing biases toward threat are linked to the development of cognitive, social, and emotional skills necessary to sustain them, which emerge during specific developmental stages in childhood. In other words, information-processing biases toward threat are not present in young children, but they emerge with developmental sophistication. Research examining cognitive development with theory-of-mind tasks and Piagetian conservation tasks has found that performance on these tasks predicted anxious interpretations and emotional reasoning scores (Muris, Mayer, Vermeulen, & Hiemstra, 2007). Thus current research seems to support an acquisition model of interpretation biases: As a child develops cognitively, his or her capacity for interpretation biases also develops. Field and Lester proposed two possible ways that trait anxiety interacts with development: (1) Anxious children develop information-processing biases as they develop the cognitive capacity for such biases, whereas nonanxious children do not; and (2) trait anxiety emerges as a result of acquiring an information-processing bias. According to Field and Lester, there is no evidence to support trait anxiety's moderating the developmental trajectory of interpretation biases, but there is research to support that anxiety is causally influenced by the acquisition of an interpretation bias (Mackintosh, Mathews, Yiend, Ridgeway, & Cook, 2006; MacLeod, Rutherford, Campbell, Ebsworthy, & Holker, 2002; Wilson, MacLeod, Mathews, & Rutherford, 2006). Clearly, more research is needed to specify these relations.

Conditioning Experiences

DIRECT CONDITIONING

Historical learning models of child anxiety date back to Pavlov's (1927/2003) classical conditioning and Watson and Rayner's (1920) demonstration of fear conditioning with Little Albert. That is, when an aversive stimulus (i.e., the unconditioned stimulus [US]; e.g., a loud noise), which elicits an unconditioned response (UR; e.g., crying), is repeatedly paired with a neutral stimulus (e.g., a white rat), over time the neutral stimulus (i.e., the conditioned stimulus [CS]) elicits a conditioned response (CR) in the absence of the US (i.e., crying upon presentation of the white rat without the loud noise). Because fear conditioning is acquired through an association between stimuli (i.e., the US and the CS), which mediates the CR, it is also referred to as "associative learning" (Davey, 1997; Field & Davey, 2001; for a thorough review, see Field, 2006). Although considerable retrospective research has found that anxious children and adults report traumatic conditioning experiences that they attribute to the onset of their symptoms (e.g., Gruner, Muris, & Merckelbach, 1999; Muris, Steerneman, Merckelbach, & Meesters, 1996; Ollendick & King, 1991; Öst & Hugdahl, 1981), less research has examined conditioning prospectively, in part due to ethical concerns about creating fears in humans. However, sophisticated research paradigms over the last two decades have allowed for the prospective examination of fear conditioning and have sought to eliminate long-term effects on participants.

Direct conditioning models that attempt to explain the development and maintenance of anxiety disorders have evolved to include individual differences in responding. Such individual differences include associative learning deficits (Grillon, 2002), greater stimulus generalization (Mineka & Zinbarg, 1996), and enhanced conditionability (Orr et al., 2000; Peri, Ben-Shakhar, Orr, & Shalev, 2000). In a meta-analysis of 20 studies of explicit threat cue learning among adults with and without anxiety disorders (N = 908), Lissek and colleagues (2005) found that relative to healthy controls, adults with anxiety acquired greater fear responses in simple conditioning paradigms in which the neutral cue (CS) was repeatedly paired with an anxiety-provoking stimulus (US), sometimes noted as CS+ and referred to as acquisition training or acquisition trials (d = 0.42). In addition, the effects of extinction training or extinction trials, in which the CS is presented without the US, was weaker among adults with anxiety

than among healthy controls ($d = 0.39$). Together, these findings suggest not only that adults with anxiety acquire fear more readily than those without anxiety, but that once this fear is conditioned, it is more difficult to extinguish in adults with anxiety disorders than adults without such disorders.

These differences between groups appear to be somewhat smaller in discrimination conditioning paradigms, in which a CS+ (e.g., tone) is repeatedly paired with a US (e.g., shock) and a CS+ (e.g., light) is never paired with the US (Lissek et al., 2005). In this paradigm, the CS– (i.e., the light) is sometimes viewed as a "safety stimulus," because it signals absence of the US, and discrimination learning is measured as the difference between the CRs to the CS+ and the CS–. Thus healthy controls should be able to suppress CRs during CS– trials and as a result should show superior discrimination learning, whereas those with anxiety disorders should demonstrate difficulty inhibiting fear even in the presence of safety cues and/or show overgeneralization from the CS+ to the CS– as a result of inability to discriminate features of the stimulus thus representing inferior discrimination learning. In the Lissek and colleagues (2005) meta-analysis, although the effect of discrimination learning was not significant during acquisition ($d = 0.08$), a nonsignificant trend emerged for discrimination learning during extinction ($d = 0.23$).

Although direct conditioning has not been as widely researched in child samples, several recent studies have examined effects of direct conditioning in youth samples and have yielded mixed findings. For instance, in a study of children ages 7–14 with and without anxiety disorders, Liberman, Lipp, Spence, and March (2006) exposed children to cartoon characters with (CS+) a very loud tone (105 dB, similar to a motorcycle or a jackhammer; US) and to different cartoon characters without (CS–) the loud tone. Children with anxiety disorders did not differentially rate the CS+ (cartoon character with the loud tone) or the CS– (cartoon character without the loud tone) as more or less fear-provoking after acquisition, but did rate the CS+ as more fear-provoking than the CS– after extinction. On the other hand, children without anxiety rated the CS+ as more fear-provoking than the CS– after acquisition but not after extinction. Furthermore, physiological measures did not evidence differential responding during acquisition trials for either anxious or nonanxious youth; however, during extinction, anxious children showed greater differential responding to the CS+ on extinction trials. Liberman and colleagues concluded that their results supported the notion that anxious children are resistant to extinction.

In another study of adolescents (mean age = 13.6 years) with and without anxiety disorders, Lau and colleagues (2008) presented adolescents with pictures of two females with neutral expressions. On some trials one of the faces was paired with a fearful face (CS+) and a loud, shrieking scream (US), while the other face remained neutral (CS–) and was not paired with the US. Lau and colleagues reported that regardless of CS type (i.e., CS+ or CS–), fear ratings were higher among anxious adolescents after acquisition trials than among nonanxious adolescents. However, across participants with and without anxiety, adolescents rated the CS+ as more fearful than the CS–, and all adolescents demonstrated greater resistance to extinction of fear ratings of the CS+ compared with the CS–.

Finally, in two additional studies, aversive conditioning among children ages 7–12 was examined using a discrimination task with two geometric figures, one paired with (CS+) and one paired without (CS–) an aversive tone (US). In the first study, Craske and colleagues (2008) found that, similar to Lau and colleagues' (2008) findings, fear responses to both CS+ and CS– were larger for anxious than for nonanxious children, but that anxious and nonanxious children showed similar levels of differential responding to the CS+ compared with the CS– during acquisition. Furthermore, similar to Liberman and colleagues' (2006) findings, anxious children in the Craske and colleagues study rated the CS+ as more unpleasant than the CS– compared with nonanxious children throughout acquisition, extinction, and a 2-week extinction retest. However, unlike Lau and colleagues and Liberman and colleagues, Craske and colleagues found that when CRs were collapsed across CS+ and CS–, anxious children demonstrated elevated CRs throughout extinction and the extinction retest. Similar to findings in the Craske and colleagues study, Waters, Henry, and Neumann (2009) found that anxious children showed larger skin conductance responses to both the CS+ and the CS– during acquisition, rated the CS+ as more arousing than the CS–, and showed greater resistance to extinction in skin conductance responses (but not arousal ratings) to the CS+ relative to the CS– compared with control children. Results from these studies provide additional support for the concept that anxious children and adolescents, similar to anxious adults, may have deficits in response inhibition to safety cues as well as delayed extinction, which may contribute to the development

of their condition. Nevertheless, given the mixed findings as well as the dearth of such research on pediatric populations, additional research in this area is needed.

CONTEXT CONDITIONING

Another type of learning involves conditioning to the situation within which the US is presented, and as such is referred to as "context conditioning." Thus, whereas explicit threat cue conditioning involves specific CSs that predict the US, in context conditioning the situation becomes predictive of the US and capable of eliciting a CR. For example, in animal studies of aversive conditioning, the animal not only becomes conditioned to the explicit CS or explicit cue (e.g., light) when it is repeatedly paired with the US (e.g., shock), but also becomes conditioned to the contextual CS or contextual cue (e.g., the cage where the shock was administered) (Blanchard & Blanchard, 1972). According to Craske, Rauch, and colleagues (2009), explicit threat cues elicit time-limited responses to imminent threat, whereas contextual cues elicit sustained anxiety responses to less certain threat. Furthermore, as noted above, some research has suggested that while the central nucleus of the amygdala may be involved in explicit threat conditioning, the BNST, the right anterior hippocampus, and the bilateral amygdala play a larger role in contextual conditioning (Alvarez, Biggs, Chen, Pine, & Grillon, 2008; Marschner, Kalisch, Vervliet, Vansteenwegen, & Büchel, 2008; Walker, Toufexis, & Davis, 2003; Yassa et al., 2012). Although context conditioning has not been as widely studied as explicit cue conditioning, the available research suggests that individuals with anxiety disorders evidence stronger conditioning to context than individuals without anxiety disorders do.

Although the research on contextual conditioning in youth with anxiety is limited, a growing body of research suggests that youth at risk for anxiety disorders may also be susceptible to contextual conditioning. For example, in a study of repeated trials of "safe–danger" sequences, adolescents high in Neuroticism demonstrated elevated startle reflex magnitude relative to individuals low in Neuroticism in conditions that were intermediately associated with threat of an aversive stimulus (i.e., biceps contraction) than in conditions that were close to the threat and in conditions that were far from the threat (Craske, Waters, et al., 2009). Craske, Waters, and colleagues (2009) interpreted these findings in light of the "strong situation" phenomenon, in which all participants (regardless of risk status) evidence enhanced startle in conditions with intense aversive stimuli, while anxious individuals evidence enhanced startle to less aversive stimuli. Similarly, all participants (regardless of risk status) evidence lower startle during baseline trials when they are reassured that no aversive stimulus will be presented, as was the case in this study. Thus this study demonstrates that adolescents high in Neuroticism are more likely to experience enhanced startle during contexts intermediary to threat than adolescents low in Neuroticism, providing initial support for the theory that adolescents with anxiety disorders, similar to adults with anxiety disorders, have a greater likelihood of conditioning to context than their nonanxious peers. Moreover, in a 4-year prospective longitudinal study of adolescents who participated in the Craske, Waters, and colleagues study, larger startle response magnitude during safe conditions predicted the first onset of anxiety disorders above and beyond the effects of comorbid depression, Neuroticism, and ratings of intensity of the aversive stimulus (Craske et al., 2012). Thus elevated startle in safe conditions or contextual conditionability may serve as a risk factor for the onset of anxiety disorders in youth.

VICARIOUS CONDITIONING AND INFORMATION TRANSFER

In addition to direct experiences with feared events or objects, indirect conditioning through observing another's fearful behavior (i.e., vicarious learning; Mineka & Cook, 1993) or through verbal communication (i.e., information transfer) is also believed to contribute to the development of fear and anxiety (Rachman, 1977). For example, toddlers show greater fear expressions and avoidance of fear-relevant and fear-irrelevant stimuli following negative reactions of their mothers (Dubi, Rapee, Emerton, & Schniering, 2008; Gerull & Rapee, 2002). Similarly, in a study of infants and their nonanxious mothers, infants were more likely to be fearful and avoidant of a stranger after watching their mothers behave in an anxious manner with the stranger than when their mothers interacted normally with the stranger (de Rosnay, Cooper, Tsigaras, & Murray, 2006). In addition to learning vicariously through parent behaviors, research has demonstrated that children can acquire fears by observing peers behaving fearfully. Broeren, Lester, Muris, and Field (2011) found that children (ages 8–10) who observed a film of a peer modeling fearful behavior toward a novel animal demonstrated increased fear beliefs about that animal (but not about a novel nonmodeled animal).

In a series of studies examining vicarious conditioning, Field, Muris, and colleagues (Askew & Field, 2007; Field & Lawson, 2003; Muris, Bodden, Merckelbach, Ollendick, & King, 2003; Muris et al., 2009) developed an innovative experimental paradigm in which children are exposed to pictures of novel animals. To test whether children can acquire a fear vicariously, Askew and Field (2007) exposed children ages 7–9 to pictures of three novel animals (Australian marsupials: the quoll, quokka, and cuscus, about which children in the United Kingdom would be unlikely to be knowledgeable) and paired these with pictures of scared facial expressions, happy facial expressions, or no faces and examined their fear cognitions and avoidance behavior. The investigators found that fearful attitudes toward the animals changed in a manner congruent with the facial expressions with which they were paired; that these beliefs persisted for up to 3 months; and that children demonstrated avoidance behavior when they believed a box contained an animal they had previously seen paired with fearful faces.

To examine whether children can acquire a fear through information transfer, Field and Lawson (2003) presented children with negative, positive, and no information about these same animals. They reported that verbal threat information significantly increased self-reported fear beliefs, emotional reaction time performance, and behavioral avoidance. These effects persisted when children were tested 6 months later (Field, Lawson, & Banerjee, 2008). Furthermore, although younger children (ages 6–8) formed stronger animal-threat and animal-safe associations as a result of information transfer than older children (ages 12–13) did, their self-reported fear and avoidance behaviors did not differ significantly from those of older children. Muris and colleagues have used a similar paradigm and have also found that providing children with negative information about novel animals results in increased self-reported fear beliefs (Muris et al., 2003) and fear-related reasoning biases (Muris et al., 2009).

Information transfer of fear has also been demonstrated with parents. Muris, van Zwol, Huijding, and Mayer (2010) gave parents of children ages 8–13 negative, positive, or ambiguous information about a novel animal. Then they gave parents open-ended vignettes describing confrontations with the animal and told parents to tell their children what would happen in these situations. Parents who received negative information about the animal described more threatening narratives of what would happen in the vignettes to their children, and these children demonstrated higher fear beliefs than children of parents who were given positive information about the animal. Furthermore, anxious parents who were given ambiguous information about the animal provided more threatening information about the animal; as a result, their children had higher fear beliefs than children of nonanxious parents who were also given ambiguous information.

Family Influences

The association between parent and child anxiety has been well established (e.g., Biederman et al., 2004; Bögels, van Oosten, Muris, & Smulders, 2001; Chavira et al., 2007; Manicavasagar, Silove, Rapee, Waters, & Momartin, 2001; Merikangas, Lieb, Wittchen, & Avenevoli, 2003; Schreier, Wittchen, Höfler, & Lieb, 2008), with recent findings suggesting that a child's risk of an anxiety disorder is 2.7 times greater when at least one parent has a lifetime history of anxiety and 4.7 times greater when at least one parent has a current anxiety disorder (van Gastel, Legerstee, & Ferdinand, 2009). However, the mechanisms underlying this relationship remain less well understood. During the past decade, a wealth of research has accumulated examining familial influences on child anxiety, prompting multiple reviews of this literature in an effort to synthesize the many (at times discrepant) findings in this area (e.g., Bögels & Brechman-Toussaint, 2006; Drake & Ginsburg, 2012; Ginsburg, Grover, & Ialongo, 2005; Rapee, 2012).

Collectively, this research has suggested numerous parenting and family variables that might be related to the development and maintenance of childhood anxiety, but few have unequivocally linked such risk factors to anxiety specifically, rather than to psychopathology more generally (Bögels & Brechman-Toussaint, 2006; Ginsburg et al., 2005). Moreover, reliance on main-effect models in this area of research, as opposed to conditional models, goodness-of-fit models (e.g., Chess & Thomas, 1989), or individual–environment interaction models, provides only a limited understanding of the relationship between dimensions of parenting and child outcome (e.g., Gallagher, 2002). Similarly, longitudinal studies that would speak to the causal mechanisms underlying the more robust associations that have been observed cross-sectionally are lacking (Rapee, 2012). Indeed, a meta-analytic review of the parenting literature specifically concluded that only 4% of the

variance in child anxiety can be accounted for by parenting (McLeod, Wood, & Weisz, 2007). However, as McLeod and colleagues (2007) and others have noted, the influence of inconsistent operational definitions, diverse measurement strategies, and varying populations examined across studies has made interpreting this literature challenging at best (e.g., Drake & Ginsburg, 2012). In spite of these challenges, however, numerous insights into the influence of family variables on childhood anxiety have been generated.

Temperament and Attachment

A recent meta-analysis of 46 studies examining the relationship between insecure attachment and anxiety reported a moderate association between these variables, with a medium effect size of 0.30 (Colonnesi et al., 2011). Insecure attachment, in addition to being associated with child anxiety, is also significantly related to high levels of BI, maternal anxiety, and parenting behaviors characterized by overcontrol and negativity, with evidence suggesting that each of these factors accounts for a unique proportion of variance in child anxiety (Hudson, Dodd, & Bovopoulos, 2011; van Brakel et al., 2006). Most recently, however, Hudson and Dodd (2012) examined a normal sample of 71 behaviorally inhibited and 89 behaviorally uninhibited children assessed initially at age 4 and again 5 years later; they found that although BI, maternal anxiety, and maternal overinvolvement significantly predicted child anxiety at follow-up even after they controlled for baseline anxiety, maternal negativity and attachment did not. These findings lend support to the predictive utility of behavioral inhibition with respect to later anxiety, but shed doubt on the role of maternal attachment. As the authors note, however, given that attachment was initially assessed at age 4, security of mother–child attachment at an earlier developmental stage might be a better predictor of anxiety later in childhood.

Several other studies have also examined BI in the context of attachment. However, whether child temperament characterized by BI interacts with insecure attachment to influence anxiety remains unclear. In addition, the distinction between temperamental and attachment variables has not been unequivocally demonstrated in the literature, and questions remain with respect to whether these variables are indeed casually related, caused by a shared third variable, or simply the same construct operationalized and assessed differently. In an investigation of BI and insecure attachment, van Brakel and colleagues (2006) reported a significant but small (accounting for less than 1% of the variance in child anxiety) interaction between these two variables, such that children classified as behaviorally inhibited and insecurely attached reported high levels of anxiety, whereas those classified as behaviorally uninhibited or securely attached endorsed low symptoms of anxiety. However, parental control also influenced this inhibition–attachment interaction (in a higher-order interaction), such that for those children classified as uninhibited and securely attached and those classified as inhibited and insecurely attached, high parental control predicted high anxiety levels; conversely, high levels of parental control were associated with low anxiety in children classified as inhibited and securely attached.

van Brakel and colleagues (2006) posit that parental control can play a positive role in child rearing by providing a child with needed structure in the context of a relationship in which the parent is sensitive to the child's needs (high BI, secure attachment). However, they also suggest that control can exert a negative effect (i.e., overprotective and restrictive parenting behaviors leading to reduced autonomy) when exhibited in the context of a relationship in which the parent is not sensitive and responsive to the needs of the child (high BI, insecure attachment) or when the child's behavior does not demand overly restrictive regulation (low BI, secure attachment). In sum, however, van Brakel and colleagues conclude that BI, attachment, and parental control appear to exert primarily additive effects upon the development of anxiety, with the observed interactions being relatively small in magnitude. Along these lines, neither Hudson and colleagues (2011) nor Hudson and Dodd (2012) observed any significant interactions between BI and specific aspects of the family environment; Hudson and colleagues suggest, however, that the effects of such an interaction might be detected only via longitudinal studies across the stages of development. Although not studied in the context of attachment security, Lewis-Morrarty and colleagues (2012) reported a significant interaction between BI and maternal overcontrol, such that high BI was associated with elevated symptoms of social anxiety only in the context of high maternal overcontrol and not under conditions of low maternal overcontrol. These results suggest that although temperamental variables can have a significant influence on the development of later anxiety, familial influences can moderate these relationships.

Parenting Behaviors

PARENTAL OVERCONTROL

Parental overcontrol has demonstrated one of the strongest links to childhood anxiety among the familial variables studied to date (Drake & Ginsburg, 2012). As noted above, in a meta-analysis of parenting variables, McLeod and colleagues (2007) found that across studies, parenting dimensions only accounted for about 4% of the variance in child anxiety. However, when they examined results at the construct level, they found that parental overcontrol accounted for 6% of the variance in child anxiety, with certain dimensions of control exerting a much larger effect on child anxiety (e.g., autonomy granting, which accounted for 18% of the variance in child anxiety). Although it is not clear whether parental overcontrol is a contributor to or a result of child anxiety (Bögels & Brechman-Toussaint, 2006), a strong relationship between these two variables has been noted from both the perspective of the child (e.g., Bögels & van Melick, 2004) and that of independent observers (e.g., Whaley, Pinto, & Sigman, 1999).

Chorpita, Brown, and Barlow (1998) sought to examine the role of children's control-related cognition in the relationship between parental control and child anxiety. Specifically, in a partial test of the model outlined in Figure 8.1, they examined whether a family environment characterized by a high degree of parental control predicted an increase in personal external locus of control, and whether that in turn predicted anxiety and elevations in the severity of anxiety. In a mixed sample of 62 children with anxiety disorders and 31 without, measures of perceived locus of control mediated between family environment and children's anxious emotion—a finding consistent with the model.

Four subsequent tests of the model proposed by Chorpita, Brown, and Barlow (1998) have been conducted to date (Affrunti & Ginsburg, 2012; Ballash, Pemble, Usui, Buckley, & Woodruff-Borden, 2006; Gallagher & Cartwright-Hatton, 2008; Nanda, Kotchick, & Grover, 2012). Although the developmental model proposed by Chorpita and Barlow (1998; Chorpita, 2001; see Figure 8.2) predicts that perceptions of control will shift from mediational to moderational in nature with advancing child age, Ballash and colleagues (2006) found support for a mediational model among a sample of young adults ages 18–25 in which perceived control acted as a mediator between family functioning and anxiety. Similarly, Affrunti and Ginsburg (2012) demonstrated that children's perceived competence partially mediated the relationship between parents' overcontrolling behaviors and the children's anxiety, suggesting that parental overcontrol might influence child anxiety by affecting the degree to which the children feel competent in their ability to successfully navigate the environment. Gallagher and Cartwright-Hatton (2008) found that, rather than parental control, overreactive parenting (a discipline style characterized as harsh, punitive,

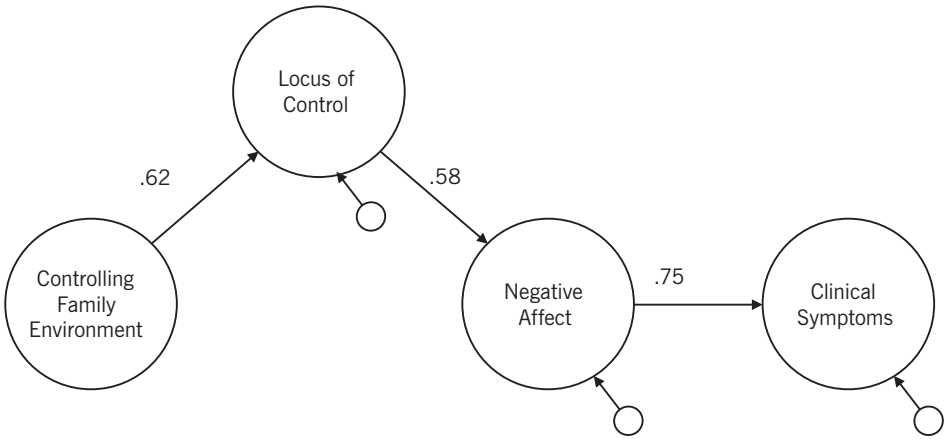

FIGURE 8.1. Model from Chorpita, Brown, and Barlow (1998): Perceived locus of control mediates parental control and child anxiety. From Chorpita, Brown, and Barlow (1998). Copyright 1998 by Elsevier. Reprinted by permission.

and inconsistent) was predictive of anxiety, and that this relationship was partially mediated by child cognitive errors, including catastrophizing, selective abstraction, overgeneralizing, and personalizing. In this study, although parental control significantly predicted child anxiety, it accounted for less variance than did overreactive parenting and was not a significant predictor when considered simultaneously with parental discipline style. Finally, Nanda and colleagues (2012) reported that children's perceived control fully mediated the relationship between parental psychological control and child anxiety, suggesting that the contribution of parental control to child anxiety is a function of its effects on a child's perceptions of control. Although supportive of not only the influence of parental control on a child's anxiety but also the importance of the child's own perceived control in this relationship, all of these studies were cross-sectional in nature and thus preclude inferences of causality.

Some more recent evidence, however, has begun to address the question of whether controlling parental behaviors generate anxiety in children, whether anxious children elicit controlling behaviors from their parents, or whether both may be true. In a longitudinal design, Edwards, Rapee, and Kennedy (2010) demonstrated that although maternal overprotection predicted later child anxiety, child anxiety also predicted subsequent maternal overprotection. In addition, evidence has suggested that it is not necessarily the anxiety status of the parent that determines whether overcontrolling behavior is emitted, but rather the anxiety status of the child. Gar and Hudson (2008) demonstrated that mothers of anxious children, regardless of whether or not they themselves had an anxiety disorder, were more overinvolved and overprotective in the context of a speech preparation task and a 5-minute speech sample; these results suggest that an anxious child might elicit certain parenting behaviors associated with overinvolvement and criticism, and that these parental factors might not be influenced by the parent's anxiety. In a subsequent test of this hypothesis, Hudson, Doyle, and Gar (2009) paired mothers of clinically anxious children and mothers of nonclinical children with a child (not their own) who was of the same anxiety classification as their own child (e.g., anxiety-disordered or not anxiety-disordered) and a child who was classified differently from their child. Mothers, regardless of their own child's anxiety status, exhibited greater levels of involvement with clinically anxious children than with nonanxious children, providing further evidence that a child's anxiety might elicit overinvolved and overcontrolled parenting behaviors. These findings suggest that future investigations of overcontrolling parental behaviors as they relate to child anxiety might be served better by examining anxious children and their parents, rather than anxious parents and their children. Interestingly, the type of task that parents and children are given to assess overcontrolling behaviors might also influence the results observed. Specifically, Ginsburg, Grover, Cord, and Ialongo (2006) noted higher levels of parental overcontrol, anxious behavior, and criticism when tasks were structured, suggesting that situational variables might also influence the interaction of parents and their anxious children.

PARENTAL REJECTION

In their meta-analytic review of the parenting literature specific to child anxiety, McLeod and colleagues (2007) conceptualize rejecting parenting behaviors as those comprising three distinct subdimensions: lack of warmth (e.g., negative and unpleasant interactions), withdrawal (e.g., an absence of involvement with or interest in the child), and aversiveness (e.g., hostility, criticism). Specifically, McLeod and colleagues ascertain that although research has historically relied upon the broad category of parental rejection to assess and define this constellation of behaviors, each subdimension might in fact be differentially related to child anxiety. Evidence from their meta-analytic review supported this notion, indicating that whereas warmth yielded a mean effect size of 0.06 (accounting for less than 1% of the variance in child anxiety) across the studies examined, withdrawal yielded a mean effect size of 0.22, and aversiveness yielded one of 0.23 (accounting for 4% and 5% of the variance in child anxiety, respectively). These results suggest that the presence of negative parenting dimensions of withdrawal and aversiveness is much more strongly associated with child anxiety than is the absence of the positive parenting dimension of warmth. Consistent with these findings, narrative reviews (e.g., Ginsburg et al., 2005) and empirical tests (e.g., Bögels et al., 2001; Lindhout et al., 2006) have also reported null findings for parental warmth, suggesting that contrary to parenting theories (e.g., Ainsworth, Blehar, Waters, & Wall, 1978; Baumrind, 1967), low parental warmth alone is not necessarily associated with heightened child anxiety. Indeed, Bögels and Brechman-Toussaint (2006) note that although low warmth itself might not be strongly associated with anxiety, the interaction of

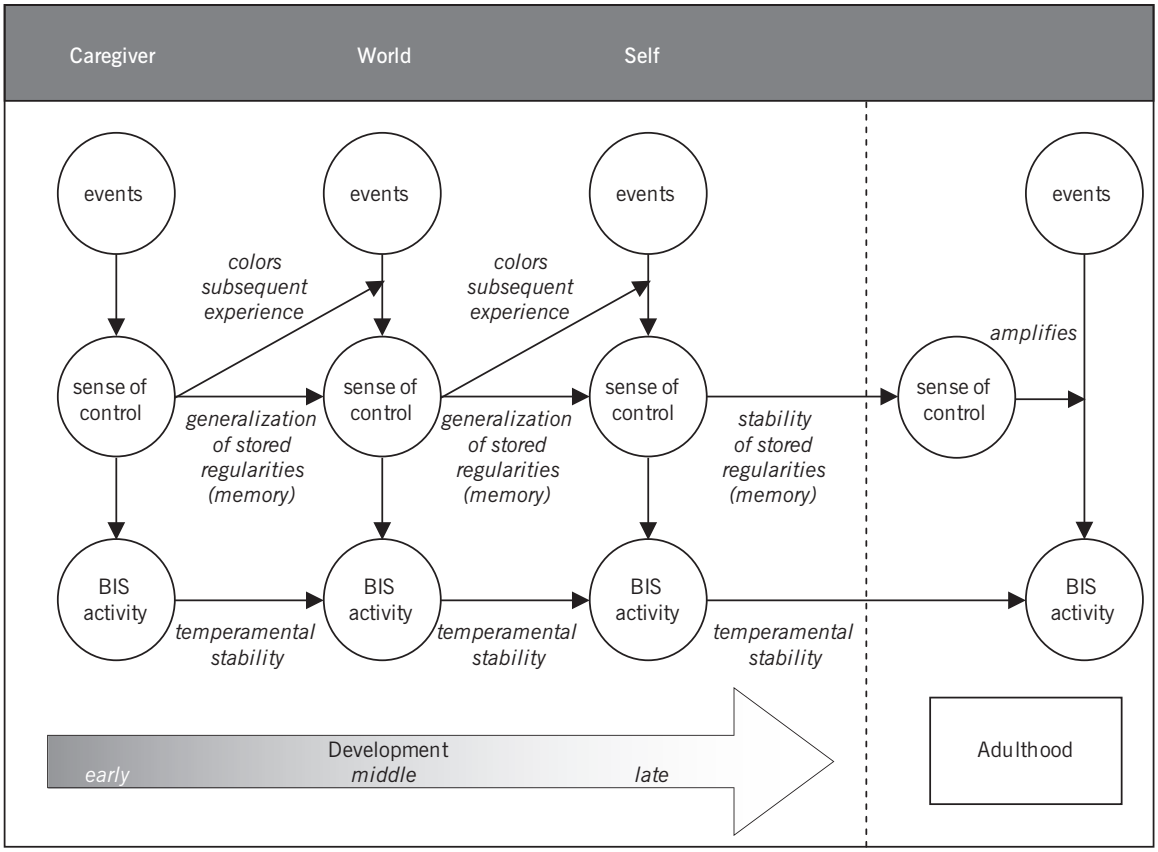

FIGURE 8.2. Model from Chorpita (2001): Perceptions of control across development. From Chorpita (2001). Copyright 2001 by Oxford University Press. Reprinted by permission.

low warmth and high control warrants further consideration in terms of its influence on child anxiety.

Consistent with McLeod and colleagues' (2007) conclusions regarding withdrawal and aversiveness, parenting behaviors defined as hostile, disapproving, and dismissive of a child (Drake & Ginsburg, 2012) have been associated with higher levels of child anxiety (e.g., Ginsburg et al., 2004). Indeed, one recent study found that not only did parents report more critical feelings toward their anxious children, but the children also perceived the parents as more rejecting, and independent raters found parents to be more critical of their anxious children than they were of nonanxious siblings (Lindhout et al., 2009). However, there is some question as to the specificity of this relationship with child anxiety rather than with psychopathology more generally (Bögels et al., 2001), and these parenting variables have been shown to account for a relatively small proportion of variance (McLeod et al., 2007). In support of the reciprocal nature of parent and child influences, however, Schrock and Woodruff-Borden (2010) reported that not only did the dyadic interaction change as a result of both partners' behavior and anxiety, but the anxiety of each partner had different effects on behavior. Specifically, they noted that whereas child anxiety would lead the child to become disengaged and interact negatively, parental anxiety prompted a more productive engagement between the dyad.

ANXIOUS MODELING

Although several studies have suggested a relationship between parental modeling of anxious and avoidant behavior and child anxiety (e.g., Barrett, Rapee et al., 1996; Chorpita et al., 1996; Dadds, Barrett, Rapee, & Ryan, 1996; Muris et al., 1996), it remains unclear whether this parenting variable actually contributes to the development of child anxiety (Rapee, 2012). Specifically, although one recent study demonstrated that anxious mothers reported high levels of anxious modeling, neither their children nor independent observers reported any differences in the anxious modeling behaviors displayed by these mothers and nonanxious mothers (Drake & Ginsburg, 2011). Yet, as Rapee (2012) notes, evidence from numerous sources has accrued to suggest a link between this parenting variable and child anxiety (e.g., Creswell, Schniering, & Rapee, 2005; Gerull & Rapee, 2002; Lester, Seal, Nightingale, & Field, 2010). This relationship has been demonstrated in the context of behavioral tasks, such that toddlers expressed more fear of a novel object after observing their mothers' negative reaction to the toy (Gerull & Rapee, 2002), as well as in questionnaire-based studies. Specifically, Creswell and colleagues (2005), among a sample of school-age children and their mothers, demonstrated that not only did mothers of anxious children endorse more threat-related interpretations to ambiguous situations, but their threat interpretations were more strongly correlated with their children's threat interpretations than with their own self-reports of general anxiety. Interestingly, subsequent to anxious children's receiving treatment for their anxiety disorders in this study, both maternal and child threat interpretations declined. In contrast to these results suggesting that mothers of anxious children endorse more threat interpretation biases, Lester and colleagues (2010) report data to suggest that children of anxious mothers also have a greater tendency toward threat interpretation. Moreover, these children also anticipated that their mothers would interpret ambiguous situations in a threatening manner and these expectations were related to the mother's anxiety levels rather than to those of the child (Lester et al., 2010). As is the case with other parenting variables, it is likely that anxious modeling interacts with child temperament (e.g., one characterized by high levels of behavioral inhibition) to influence child anxiety, such that children prone to fearfulness will experience higher levels of anxiety after being exposed to parental modeling of anxious behaviors (Barrett, Rapee, et al., 1996; Chorpita et al., 1996; de Rosnay et al., 2006).

PARENTAL COGNITIONS

Bögels and Brechman-Toussaint (2006), in their review of the parenting literature, suggest that research investigating the relationship between parents' beliefs about their children's coping abilities, anxious behaviors, and potential for success in challenging situations is in the early stages of its development, but has the potential to shape theories of anxiety and its transmission. Indeed, research from multiple sources has suggested that parents of anxious children perceive their children's ability across a variety of domains more negatively than do parents of nonanxious children (e.g., Micco & Ehrenrich, 2008). However, it has been hypothesized that such expectations might influence the children's anxiety only when they are directly and explicitly communicated to the children (Becker & Ginsburg, 2011), as has been demonstrated in previous investigations (e.g., Barrett, Rapee, et al., 1996; Chorpita et al., 1996).

PARENTAL ANXIETY AND PARENTING BEHAVIORS

Although anxious mothers report less warmth, more anxious modeling, and even heightened levels of distress when watching their children engage in "risky" play, these reports are not corroborated by either child reports or independent observers' ratings (Drake & Ginsburg, 2011; Lindhout et al., 2006; Turner, Beidel, Roberson-Nay, & Tervo, 2003). Indeed, recent evidence suggests that child anxiety, rather than parental anxiety, might elicit parenting behaviors that have been associated with anxiety (e.g., Hudson et al., 2009). Interestingly, Kiel and Buss (2010) observed that the relationship between toddlers' fearful temperament (e.g., seeking close proximity to their mothers, wanting to be held) and mothers' protective behaviors (e.g., shielding the children from an activity) was moderated by the degree of accuracy with which mothers predicted their toddlers' fearful behaviors. Specifically, toddler fearful temperament was associated with heightened maternal protectiveness when mothers had a high degree of accuracy in predicting, and thus were much attuned to, their children's behavior (Kiel & Buss, 2010). The authors conclude that high levels of fearful child behavior do elicit protective behaviors from mothers, but only in the context of mothers who are attuned to their children's behavior, suggesting that both child and

maternal characteristics play an important role in the dyadic interaction.

Family Environment

Numerous aspects of the family environment have been examined in relation to child anxiety, including cohesion, adaptability, and conflict. Although both high (e.g., Peleg-Popko & Dar, 2001) and low (e.g., Turner et al., 2003) cohesion have been associated with anxiety, there is little evidence for the specificity of this relationship (Bögels & Brechman-Toussaint, 2006). Similarly, both high (Teichman & Ziv, 1998) and low (Barber & Buehler, 1996) levels of adaptability have been associated with child anxiety, suggesting that the relationship between these family variables and child anxiety might be nonlinear or might interact with other parental, child, and familial variables to influence child anxiety. Ginsburg and colleagues (2004), in their review of the literature, reported that only two of five studies examining the influence of family conflict on child anxiety found positive associations. Rapee (2012) similarly notes that there is currently little evidence to support the specificity of this relationship, indicating that improved measurement and longitudinal studies are required to draw firm conclusions regarding the role of family conflict in child anxiety.

As a specific facet of the family environment, marital conflict and quality have also been examined in relation to child anxiety. Although some studies have suggested that marital satisfaction specifically predicts child anxiety over time (e.g., McHale & Rasmussen, 1998), others have reported no differences in parent-reported marital quality between parents with and without anxiety-disordered children (e.g., Siqueland, Kendall, & Steinberg, 1996). Although parental divorce has also been linked with child anxiety (Lansford et al., 2006), this association might be explained by interparental conflict, which can both precede and follow the separation (Rapee, 2012).

Cultural Variations

Investigations of the cultural aspects of childhood anxiety play an important role in determining which patterns of behavior are universal and which might be specific to particular groups or settings. By highlighting possible determinants of anxiety not accounted for by existing biological and psychosocial theory, cross-cultural perspectives help to clarify the underlying validity of our present conceptualization of childhood anxiety.

Cross-Cultural Differences in Self-Reported Anxiety

Among the self-report assessment measures studied most widely cross-culturally, two are more traditional measures of general levels of fear and anxiety, respectively (the Fear Survey Schedule for Children—Revised [FSSC-R; Ollendick, 1983] and the STAIC [Spielberger, 1973]). Three measures developed within the past 20 years and mentioned earlier in this chapter assess childhood anxiety dimensionally—two in a manner consistent with DSM-IV-TR diagnostic categories (the SCAS [Spence, 1998] and the SCARED [Birmaher et al., 1997]), and one designed to measure four theoretically derived dimensions of anxiety (the MASC [March, Parker, Sullivan, Stallings, & Conners, 1997]).

The FSSC-R, an 80-item inventory of different fear stimuli and situations, has been used to assess differences in patterns of childhood fears across numerous cultural groups. The FSSC-R has been translated into a variety of languages and administered to children and adolescents in the United States, Portugal, Italy, Turkey, Australia, the Netherlands, Northern Ireland, China, and the United Kingdom (see Fonesca, Yule, & Erol, 1994, for a review). Examination of the main differences across groups is limited to those groups that have received the same 80-item adaptation—that is, Australia, the United States, the United Kingdom, Portugal, China, and the Netherlands. Results showed relatively similar scores for most of these countries; however, the Dutch sample scored lower and the Portuguese sample scored higher than the other countries on total fear (Fonesca et al., 1994). One explanation offered to explain this difference is that the tendency for Latin cultures is to express fears more spontaneously, whereas Nordic cultures tend to control or conceal emotions (Fonesca et al., 1994). Across all groups, girls were found to score higher than boys. This does not necessarily imply a universal, "culture-free" gender pattern for fears, however, because the role of women in these cultures is fairly homogeneous and may involve a higher risk for the development of anxiety (cf. Nolen-Hoeksema, 1987).

Examination of the most common fears across cultures with the FSSC-R shows striking commonalities. Children in the United Kingdom, the United States, Turkey, Portugal, and Australia all shared the fear of being hit by a car as the most frequently endorsed childhood

fear. Fears of not being able to breathe, a bomb attack or war, fire, a burglar, falling from a height, and death ranked in the top 10 fears of at least four of these countries. In addition, items appended to the original 80-item measure revealed that fear of a parent's death was considerable in all countries tested (United Kingdom, Turkey, Portugal), with endorsement ranging from 73 to 84% (Fonesca et al., 1994).

In a manner similar to the work of Ollendick and colleagues, Spielberger and colleagues (Spielberger & Diaz-Guerrero, 1983; Spielberger, Diaz-Guerrero, & Strelau, 1990) have fostered research examining self-reported trait anxiety across different cultures. The STAIC measures general anxiety in school-age children and has two subscales—a Trait Anxiety scale, which measures general trait anxiety or proneness to negative affect, and a State Anxiety scale, which measures transient negative emotional state. At present, the majority of the cross-cultural research with the STAIC has involved validation of the instrument in a variety of countries. Currently, adaptations have been developed for Polish, Hungarian, Russian, Jordanian, Lebanese, and Bengali samples, most of which consisted of students in middle to late adolescence. In one comparative study, Ahlawat (1986) found similar factor structures between the Arabic STAIC and the American version (i.e., factor analysis supported a two-factor structure with the Trait Anxiety and State Anxiety scales in both samples). In addition, sex differences were similar to those found in the United States, with girls scoring higher on Trait Anxiety than boys. In general, support for the use of the STAIC across different cultures has been demonstrated.

The SCAS is a 38-item self-report questionnaire designed to assess DSM-IV-TR symptoms of GAD, SAD, social phobia, panic disorder and agoraphobia, obsessive–compulsive disorder, and specific phobia. The SCAS has been evaluated among numerous cultural groups, including Japanese, German, South African, Dutch, Hong Kong Chinese, Colombian, and Greek children and adolescents (e.g., Crane Amaya & Campbell, 2010; Essau, Ishikawa, & Sasagawa, 2011; Essau, Ishikawa, Sasawaga, Sato, et al., 2011; Essau, Leung, Conradt, Cheng, & Wong, 2008; Essau, Muris, & Ederer, 2002; Essau, Sakano, Ishikawa, & Sasagawa, 2004; Ishikawa, Sato, & Sasagawa, 2009; Li, Lau, & Au, 2011; Mellon & Moutavelis, 2007; Muris, Merckelbach, Ollendick, King, & Bogie, 2002; Muris, Schmidt, Engelbrecht, & Perold, 2002). Investigations using the SCAS across these cultural groups have yielded relatively consistent evidence with respect to sex differences (girls score significantly higher than boys on all scales), internal consistency (high and comparable to that observed in the validation sample), and factor structure (adhering to the six-correlated-factor structure initially obtained by Spence, 1998).

One group among whom the proposed SCAS factor structure was not supported was South African school children. Specifically, Muris, Schmidt, and colleagues (2002) reported that in their sample of South African children, three key differences in the factor structure of the SCAS were observed: (1) Items representing generalized anxiety and obsessive–compulsive symptoms loaded on the same factor; (2) items assessing separation anxiety loaded on multiple factors; and (3) a factor for school phobia was not identified. In addition, the levels of anxiety reported by South African children (in particular, those related to compulsive behaviors and physical separation from parents) were higher than not only those of the Dutch children to whom they were directly compared in this study, but also those of the Western children assessed in previous psychometric studies of the SCAS (Muris, Schmidt, et al., 2002). Greek children have also been observed to endorse markedly higher levels of anxiety than children in other cultures, with particularly high rates of endorsement for items pertaining to social phobia and obsessive–compulsive behaviors (Mellon & Moutavelis, 2007).

With respect to cross-cultural differences in the endorsement of specific SCAS items, Japanese children, relative to those in Western countries studied more often endorsed items related to obsessive–compulsive symptoms (e.g., checking to make sure things have been completed correctly) and specific fears (Ishikawa et al., 2009). In addition, the social phobia items most frequently endorsed by Japanese children in this study referred to fears of negative evaluation, whereas those most commonly endorsed by Australian children pertained to tests and speeches (Ishikawa et al., 2009). When compared directly with adolescents from England, Japanese adolescents, in two separate studies, scored significantly lower in self-reported anxiety (Essau, Ishikawa, & Sasagawa, 2011; Essau, Ishikawa, Sasawaga, Sato, et al., 2011). German children, when compared to Japanese children, have also been reported to endorse significantly greater levels of separation anxiety, social phobia, obsessive–compulsive disorder, and GAD, although Japanese children reported relatively more symptoms related to physical injury (specific) fears (Essau et al., 2004). Conversely, when com-

pared with Hong Kong Chinese adolescents, German adolescents reported significantly fewer symptoms of anxiety on the SCAS total anxiety scale as well as on each of the subscales (Essau et al., 2008). Finally, symptoms endorsed by Dutch children on the SCAS have been reported to be lower than those endorsed by Australian children (Muris, Schmidt, & Merckelbach, 2000), whereas those reported by Colombian children have been higher than those of their Australian counterparts (Crane Amaya & Campbell, 2010).

The SCARED, a 41-item self-report measure, was, (like the SCAS) designed to assess symptoms of anxiety consistent with DSM-IV-TR diagnostic categories, including GAD, SAD, social phobia, panic disorder, and school phobia. The psychometric properties of the SCARED have been evaluated among Belgian, Dutch, German, Italian, South African, and Chinese children and adolescents (see Hale, Crocetti, Raaijmakers, & Meeus, 2011, for a meta-analytic review of these studies). Across studies employing the SCARED, girls consistently score higher than boys on all scales, with the exception of the school anxiety scale on which sex differences are not observed. In addition, the four-factor structure of the SCARED, assessing symptoms of GAD, panic and agoraphobia, SAD, and social phobia, has been well supported in numerous cultures, although less consistent support has been obtained for the school anxiety factor of this scale. Indeed, Hale and colleagues (2011) suggest that the structure of symptoms of the DSM-IV-TR anxiety disorders is quite consistent cross-culturally when evaluated using the SCARED.

The MASC is a 39-item self-report instrument that was initially developed to assess four theoretically derived dimensions of child anxiety—namely, affective, physical, cognitive, and behavioral. Factor-analytic studies, however, have suggested that the items of this scale assess dimensions of physical symptoms, social anxiety, separation anxiety, and harm avoidance. The MASC has been translated and its psychometric properties evaluated among samples of Dutch, Taiwanese, Mexican, Chinese, and Icelandic children (Muris, Merckelbach, et al., 2002; Olason, Sighvatsson, & Smari, 2004; Varela, Sanchez-Sosa, Biggs, & Luis, 2008; Yao et al., 2007; Yen et al., 2010). Across the cultural groups studied using the MASC, the factor structure and reliability estimates observed have been consistent with those obtained in the initial validation sample. Similar to studies employing other measures of anxiety, girls consistently score higher than boys on the scales of the MASC. Although the mean levels of anxiety endorsed by Icelandic children (Olason et al., 2004) were similar to those reported by American (March et al., 1997) and Dutch (Muris, Merckelbach, et al., 2002) samples, specific differences have been noted for other groups. Specifically, Taiwanese children generally reported more social anxiety than their American counterparts, as well as higher levels of separation/panic; conversely, Taiwanese children generally reported lower levels of harm avoidance and physical symptoms than did American children (Yen et al., 2010). Both Mexican children and other Latino children residing in the United States more frequently endorsed worries and somatic symptoms than did European American children (Varela et al., 2008). Finally, Chinese children endorsed higher levels of social anxiety (on both the humiliation/rejection and public performance subscales) and separation anxiety/panic on the MASC than did the American normative sample (Yao et al., 2007).

Cross-Cultural Differences in Test Anxiety

Guida and Ludlow (1989) examined the phenomenon of test anxiety in children from different cultural groups; they evaluated the effects of SES, child gender, and cultural background on self-reported test anxiety. Using the Test Anxiety Scale for Children (Sarason, Davidson, Lightfall, Waite, & Ruebush, 1960), the investigators compared samples of low-SES urban African American children, middle-SES American children, upper-SES American children, and a large sample of Chilean students. In the comparative analyses, the Chilean students scored higher on test anxiety than the American samples. Across groups, children with high SES scored lower on the measure than children with low SES. Within low-SES children, there was also a tendency for girls to score higher than boys on the test anxiety measure.

Using the Spielberger Test Anxiety Inventory (Spielberger, 1980) and the FRIEDBEN Test Anxiety Scale (Friedman & Bendas-Jacob, 1997), Bodas, Ollendick, and Sovani (2008) evaluated test anxiety in a sample of Indian school children. They observed lower levels of self-reported test anxiety among these middle and high school children (ages 10–15), relative to American children as well as children evaluated in other cultures. In this sample, girls did not endorse higher levels of test anxiety than did boys, and no age differences were noted on the Test Anxiety Inventory (Bodas et al.,

2008). Although the absence of significant age differences is consistent with findings reported elsewhere with respect to test anxiety, the lack of sex differences is not (Bodas et al., 2008).

In a comparison of levels of test anxiety reported by Arab and Jewish students in Israel, using Friedman and Bendas-Jacob's (1997) Hebrew-language Test Anxiety Questionnaire, Arab 10th- and 11th-grade students were observed to report significantly higher levels of test anxiety than their Jewish counterparts (Peleg-Popko, Klingman, & Nahhas, 2003). Girls in both cultural groups endorsed higher levels of test anxiety on this measure than did boys, and a significant association between family environment and test anxiety was observed: More authoritarian styles of parenting were associated with higher test anxiety, and more supportive parenting styles were associated with lower test anxiety (Peleg-Popko et al., 2003). These authors indicated that the cultural differences observed with respect to test anxiety in this study mirror those reported elsewhere (i.e., individuals from Eastern cultures report more test anxiety than do those from Western cultures), suggesting that such differences might reflect cultural variations in the importance of tests for educational and professional advancement (Peleg-Popko et al., 2003).

Consistent with these findings, Essau and colleagues (2008) reported that whereas academic motivational goals (including competition to achieve good grades and a desire to be rewarded for good performance) were correlated with anxiety symptoms reported by Hong Kong adolescents, for German adolescents significant correlates of anxiety included being reinforced for anxious symptoms and parental communication about the potentially harmful nature of anxiety. Accordingly, these authors suggest that anxiety among Hong Kong adolescents appears to be related to extrinsic pressures to succeed, whereas for German children learning experiences within the family shape the experience of anxiety (Essau et al., 2008). Similarly, Greek adolescents self-reported significantly higher levels of anxiety and depression than Finnish adolescents, which the authors attributed to the high value placed on educational attainment and success in Greece (Kapi, Veltsista, Sovio, Järvelin, & Bakoula, 2007). However, although both of these studies suggest that perceptions of external pressure to meet familial standards of excellence might be associated with higher levels of anxiety, Essau, Ishikawa, Sasagawa, Sato, and colleagues (2011) suggest otherwise. Specifically, these authors found that although interdependent self-construal (i.e., perceiving oneself in a collectivistic sense and seeking to make one's behaviors and thoughts consistent with those of the group) was associated with higher anxiety for both English and Japanese children (and independent self-construal [i.e., perceiving oneself in an individualistic sense and pursuing autonomy and individual achievement] was associated with lower anxiety for both groups), this relationship was actually weaker for Japanese adolescents, suggesting that perceptions of connectedness to one's social group are not necessarily linked to poorer outcomes (Essau, Ishikawa, Sasagawa, Sato, et al., 2011).

Cross-Cultural Differences in Anxious Symptoms and Syndromes

In an investigation of cultural influences on general child pathology, Weisz and colleagues (1987) used the CBCL to compare American children with children living in Thailand. The general pattern suggested that the Thai children manifested more internalizing behavior (e.g., being withdrawn, anxious, or depressed) than did the American children. In a follow-up to this study, however, Weisz, Weiss, Suwanlert and Chaiyasit (2003) noted that the individual problems constituting the narrow-band factors of the CBCL were not perfectly comparable across cultures, particularly for the Anxious and Depressed scales, which were only moderately comparable across groups. Accordingly, the authors revised their original conclusions to indicate that Thai children have a higher prevalence of specific individual internalizing problems and certain narrow-band syndromes for which the items are highly comparable across cultures (e.g., the Somatic Complaints scale). The high degree of similarity with respect to somatic problems across cultures suggests either that these problems are quite consistent in these two different groups, or that physical problems might be in some way distinct from the psychological problems assessed by the other scales of the CBCL (Weisz et al., 2003).

With respect to somatic concerns, numerous recent studies have examined the prevalence and correlates of somatic complaints in Latin American children specifically. A potentially culture-bound syndrome, *ataques de nervios* (AdN), is a clinical presentation that in adults is comprised of symptoms closely related to panic attacks, including feeling out of control, trembling, crying, and fainting. An AdN is distinguished from a panic

attack by the fact that it is often preceded by an identifiable stressful event and is not typically associated with feelings of fear or apprehension (Guarnaccia, Martinez, Ramirez, & Canino, 2005). In an epidemiological study of Puerto Rican children ages 4–17, Guarnaccia and colleagues (2005) observed prevalence rates of 9% in a community and 26% in a clinical sample. In both groups, a higher prevalence of AdN was noted for girls than for boys; a family history of AdN was associated with a child's experience of an AdN (although a family history of mental illness was not); and children experiencing AdN were at greater risk of also meeting diagnostic criteria for a psychiatric disorder. Although it was hypothesized that the relationship between AdN and diagnoses of anxiety would be the strongest, given the resemblance of AdN to panic attacks observed in adults, in this study children experiencing an AdN had the highest odds of being diagnosed with any depressive disorder. However, among the anxiety disorders, the greatest risk for a psychiatric disorder was associated with panic disorder: Children in the community who had experienced an AdN were 31 times more likely to meet diagnostic criteria for panic disorder (Guarnaccia et al., 2005).

More generally, Latino children have been reported to experience higher levels of somatic symptoms than European American children, even after investigators have controlled for potentially confounding variables such as SES and family income (e.g., Pina & Silverman, 2004; Varela et al., 2004). Mexican and other Latino children in their own countries also report higher levels of anxiety symptoms compared with their European American counterparts in the United States, suggesting that heightened levels of anxiety observed among Latin American children are not simply a function of belonging to an ethnic minority group (Varela et al., 2004).

Finally, in an investigation of the cross-cultural applicability of the tripartite model of emotions (Lu et al., 2010), children and adolescents ages 9–18 of European American, Japanese American, Chinese American, and Chinese national descent received the Affect and Arousal Scale for Children (Chorpita, Daleiden, et al., 2000). Although no differences on any of the tripartite dimensions (NA, PA, PH) were noted for the American cultural groups, the Chinese national children reported significantly lower levels of NA and PA than did the American children. The authors concluded that the structure of emotions as posited by the tripartite model and measured by this scale was consistent across the cultures assessed.

Parenting Behaviors, Child Anxiety, and Cultural Differences

Several investigations have examined the role that parental practices might play in the expression of anxiety and somatic concerns among Latino children (Luis, Varela, & Moore, 2008; Varela et al., 2004; Varela, Sanchez-Sosa, Biggs, & Luis, 2009). Varela and colleagues (2004) reported that Mexican and Mexican American parents, relative to European American parents, verbalized more somatic, nonanxious interpretations of ambiguous scenarios during family discussions, and that Mexican parents made fewer anxious, nonsomatic interpretations than did European American parents. These results supported the hypothesis that somatic expressions of emotion might be more culturally acceptable for families of Hispanic descent (Varela et al., 2004). Luis and colleagues (2008) noted that although controlling parenting practices were associated with higher levels of child anxiety for Mexican and European American families, such practices were associated with lower levels of anxiety for Mexican American families. However, Mexican American parents made more controlling statements than Mexican parents and more statements associated with low warmth and acceptance than European American parents, suggesting that in this sample the relation between controlling parenting style and child anxiety was not culturally moderated (Luis et al., 2008). Varela and colleagues (2009) observed that maternal control was associated with higher levels of anxiety for both European and Latin American children (Mexican children were not included in this analysis), and that maternal acceptance was also significantly associated with high child-reported anxiety for European and Latin American children, but that the reverse was true for Mexican children. However, the relationship between maternal acceptance and child anxiety, when examined by cultural group, was significant only for the Latin American children, suggesting that Latin American mothers demonstrating high levels of acceptance might also offer reassurance to their children and potentially reinforce the children's expression of anxious symptoms (Varela et al., 2009).

In an investigation of the effects of parenting practices on anxiety among Japanese and English adolescents, Essau, Ishigawa, and Sasagawa (2011) observed no significant differences with respect to parental reinforcement or punishment for anxiety symptoms; in both countries, less parental punishment of anxious symptoms was associated with higher reports of

adolescent anxiety. However, whereas English parents were more likely to punish non-anxiety-related physical symptoms, Japanese parents were more likely to reinforce such symptoms, suggesting that the presence of somatic (in contrast to affective) symptoms are more easily tolerated in this Asian cultural group.

Finally, Muris and colleagues (2006) investigated the relationship among parental anxious rearing, overprotection, and rejection and child anxiety in a sample of South African children. This sample consisted of children and adolescents from the primary cultural groups of the Western Cape of South Africa and included white youth, black youth, and youth of mixed ethnic heritage. (Muris et al., 2006, labeled this third group "colored," as this term is still common in this region; they attribute this to South Africa's racialist past.) These authors observed lower levels of child-reported parental anxious, overprotective, and rejecting behaviors, and higher levels of parental warmth, for white children than for mixed-heritage and black children; for all groups, anxious rearing, overprotection, and rejection were associated with elevated levels of child anxiety. However, parents' occupational level fully accounted for group differences in perceptions of overprotective parental behaviors, suggesting that the family living conditions of low-SES families might be responsible for overprotective parenting behaviors, rather than cultural differences between these groups.

Cross-Cultural Differences in Anxiety Disorder Prevalence Rates

Cross-cultural prevalence estimates for the DSM-IV anxiety disorders have been reported in the context of epidemiological surveys of psychopathology more generally. Across these studies, anxiety disorders typically emerge as the second most prevalent diagnostic category in the population studied, following diagnoses of disruptive behavior disorders (e.g., Anselmi, Fleitlich-Bilyk, Menezes, Araújo, & Rohde, 2010; Fleitlich-Bilyk & Goodman, 2004; Gau, Chong, Chen, & Cheng, 2005). Specifically, among a sample of Brazilian children (ages 11–12), Anselmi and colleagues (2010) reported a prevalence estimate of 6.0% for any anxiety disorder; Fleitlich-Bilyk and Goodman reported a prevalence of 5.2%, also among Brazilian children (ages 7–14). Similarly, Gau and colleagues (2005) estimated the prevalence of any anxiety disorder among a sample of Taiwanese children to range from 9.2% for children in grade 7 to 3.1% for children in grade 9. Several additional investigations have reported comparable prevalence rates across a wide range of cultural groups, including Hong Kong Chinese adolescents (6.9%; Leung et al., 2008), Irish adolescents (3.7%; Lynch, Mills, Daly, & Fitzpatrick, 2006), Bangladeshi children (8.1%; Mullick & Goodman, 2005), Scottish adolescents (5.9%; West, Sweeting, Der, Barton, & Lucas, 2003), and Puerto Rican children and adolescents (6.9%; Canino et al., 2004). In those studies for which prevalence estimates for the individual anxiety disorders were reported (e.g., Canino et al., 2004; Fleitlich-Bilyk & Goodman, 2004; Gau et al., 2005; Heiervang et al., 2007; Leung et al., 2008; Mullick & Goodman, 2005; West et al., 2003), rates were relatively consistent across cultural groups.

In addition, across the cultural groups studied, girls have consistently been more frequently diagnosed with anxiety disorders than boys (e.g., Fleitlich-Bilyk & Goodman, 2004; West et al., 2003). Another common theme observed across these studies is the importance of using an impairment criterion in determining diagnostic status (e.g., Canino et al., 2004; Leung et al., 2008; West et al., 2003). Specifically, many studies reported elevated levels of anxiety disorders in certain cultural groups when questionnaire-based assessments were used. However, when researchers used diagnostic measures that apply an impairment criterion, the rates of anxiety disorders became markedly lower and more consistent with those reported in other cultural groups. For example, when relying simply on symptom counts using the computerized Voice version of the Diagnostic Interview Schedule for Children (Voice-DISC; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000), West and colleagues (2003) reported a prevalence estimate of 9.2% for any anxiety disorder among Scottish adolescents; this estimate was reduced to 5.9% when an impairment criterion was applied, however. Similarly, using only symptom criteria with the Spanish version of the DISC-IV (Bravo et al., 2001), Canino and colleagues (2004) reported prevalence rates for any anxiety disorder of 9.5%; when impairment criteria specific to each disorder were applied, the observed prevalence estimate was 6.9%.

THEORETICAL FRAMEWORKS AND POSSIBLE DEVELOPMENTAL PATHWAYS

Historically, models of childhood anxiety have tended to be unidimensional, focusing on only one aspect (e.g., learning theories, cognitive theories). Moreover, such

models were often adapted from models of adult psychopathology and failed to take into account the critical changes that occur during the course of children's physical, cognitive, and socioemotional development. More recent theories have become increasingly complex and integrate multiple interactive concepts, including biological, psychological, and environmental contributors to psychopathology. One example of such a theory is Barlow's (2002) triple-vulnerability model of anxiety, which posits that generalized biological, generalized psychological, and specific psychological vulnerabilities together place an individual at risk for developing an anxiety disorder. Similarly, models of psychopathology suggested by Pine (2009) incorporate data from genetic research, information-processing paradigms, cognitive and affective neuroscience research, and brain imaging studies to provide a framework for understanding anxiety disorders in children. Theories such as these recognize the transactional nature of the development of anxiety. They evaluate the contributions of not only the child and specific aspects of the environment (e.g., parents, peers, community), but also the dynamic interaction of these variables across the various stages of development (e.g., Vasey & Dadds, 2001). Indeed, it is now more generally acknowledged that rather than serving as causal variables, factors such as specific parenting practices exist in a bidirectional relationship with specific child characteristics such as temperament (e.g., Edwards et al., 2010; Gar & Hudson, 2008; Hudson et al., 2009).

As theories of child anxiety continue to emerge and evolve, it is imperative that they continue in the direction of integrating the findings currently being generated from the genetic, biopsychological, conditioning, and cognitive literatures. For example, in a review of the literature examining genetic contributions to environmental variables that influence psychopathology (including social support, parenting behavior, family environment, peer interactions, and stressful life events), Kendler and Baker (2007) report significant heritability estimates for parenting behaviors such as warmth. Moreover, this research suggests that both parent and child genes contribute to the parent–child relationship. Although such findings might suggest that parenting behaviors are genetically determined, they do not preclude the role of psychosocial variables. More specifically, a heritability estimate of 35% for parental warmth leaves room for other influences, including those from the environment, to affect outcomes.

Collectively, the literature supporting multidimensional theories of child anxiety not only illustrates the multiplicity of etiological influences contributing to childhood anxiety disorders (e.g., genetic, neurobiological, temperamental, psychosocial, familial), but also suggests numerous targets of intervention that change across time and with development. For example, although interventions aimed at parenting practices have demonstrated efficacy in the treatment of childhood anxiety disorders (e.g., Barrett, Dadds, & Rapee, 1996; Wood, Piacentini, Southam-Gerow, Chu, & Sigman, 2006), the impact of these interventions may change over time as peers become an increasingly important part of adolescence.

CONCLUSIONS AND FUTURE DIRECTIONS

More than 10 years have passed since the previous edition of this chapter was published, and in that time there has been a remarkable and unprecedented growth in the empirical knowledge regarding childhood anxiety disorders. Although the revisions to DSM that have been made during this period are important, they focus primarily on the symptoms and structure of the disorders, and thus significantly understate the wealth of new discoveries on this topic. We now have greater insight than ever before into the biological, genetic, conditioning, cognitive, familial, and ecological issues relevant to childhood anxiety and its disorders.

Many of these diverse findings organize themselves around two central themes. First, there is an increasing awareness of the importance of endophenotypes, intermediate dimensions or syndromes, and the hierarchical relations among the constructs relevant to anxiety. Much of the developmental continuity and discontinuity in anxiety syndromes and disorders can be best explained by understanding the risk and protective effects that involve such dimensions as BI, PA/NA, EC, and individual differences in conditionability and information processing. Second, current findings increasingly suggest that main effects are the exception rather than the rule, and that the development of anxiety and its disorders is frequently characterized by transactional effects (e.g., anxious children elicit different parenting styles than nonanxious children do), moderational models (e.g., individual differences in conditioning or baseline inhibition levels moderate the effects of experience on emotionality), feedforward models (e.g., hypercortisolism has long-term effects on neurohormonal regulation), or combinations of many of these.

Science often proceeds through cycles of generation and consolidation, and in our view, the field of child-

hood anxiety disorders has experienced an unprecedented generative period over the past 15 years. There are extensive and relatively independent literatures on cognitive, behavioral, biological, environmental, and genetic issues, among others. Going forward, research on childhood anxiety may be well served by attempts to consolidate and reconcile these varied and extensive new findings into parsimonious models or theories. Such attempts may foster integrative biopsychosocial experimentation that bridges what often remain independent literatures (e.g., genetic studies of intermediate dimensions other than end-state disorders; studies of the effects of culture on the interaction of cognition and affect). This work will likely require continued attention to understanding the basic constructs (and how best to measure them), as well as increased longitudinal research to tease out how these dimensions truly interact over development. Although our field does not have all the answers at the moment, the next decade's important questions—albeit more complex than we had hoped—are now at least clearly in sight.

NOTES

1. We use the terms "child," "children," and "childhood" throughout the chapter to refer to all children and adolescents, regardless of age, unless otherwise noted.

2. In DSM-IV, the former OAD (from DSM-III-R) was subsumed under the revised GAD, and hence our understanding of the symptoms and clinical presentation of GAD in children is based largely on studies of children with OAD. Research indicates minimal and nonsignificant differences between the DSM-III-R and DSM-IV criteria; experts have thus suggested that past research on OAD can be applied to understanding GAD in youth (e.g., Kendall & Warman, 1996; Tracey, Chorpita, Douban, & Barlow, 1997).
